Outlier
Poor LRL (concentrations <LRL with LRL > maximum detected concentration).
Poor LRL for many parameters for a particular sample so all PAH values for that sample removed.

Outlier
Poor LRL (concentrations <LRL with LRL > maximum detected concentration).
Poor LRL for many parameters for a particular sample so all PAH values for that sample removed.

Table E.7: Summary Statistics for the Reference Area Data used to Define Reference Normal Ranges for Individual Sediment Samples, 2013 and 2015

Estimates of the reference area normal range
Upper limit of nomal range exceeds the Lower SQG
Upper limit of nomal range exceeds the Upper SQG

[a] A concentration that will protect aquatic life from adverse effects of toxic substances in most situations.
[b] A concentration that if exceeded will likely cause severe effects on aquatic life.
[c] Only a single guideline has been defined.

	ELKO	0.631	0.797	84	0.79	0.431	0.018	0.279	0.585

[a] Contrasts test the hypothesis: $[3(\mu_{E(2015)})- (\mu_{R1(2015)}+\mu_{R2(2015)}+\mu_{R3(2015)})] - [3(\mu_{E(2013)})- (\mu_{R1(2013)}+\mu_{R2(2013)}+\mu_{R3(2013)})]=0$ where $\mu_{E(j)}$ = mean for the mine-exposed area in year j and $\mu_{Ri(j)}$ = mean of reference area i in year j

[b] Estimate of $[3(\mu_{E(2015)})- (\mu_{R1(2015)}+\mu_{R2(2015)}+\mu_{R3(2015)})] - [3(\mu_{E(2013)})- (\mu_{R1(2013)}+\mu_{R2(2013)}+\mu_{R3(2013)})]$. A positive estimate indicates that the mine-exposed mean in 2015 is greater than predicted if the mine-exposed area had a trend equal to the mean reference area trend.

Note: Magnitude of difference not reported for PC-1 due to scale

P-value < 0.05

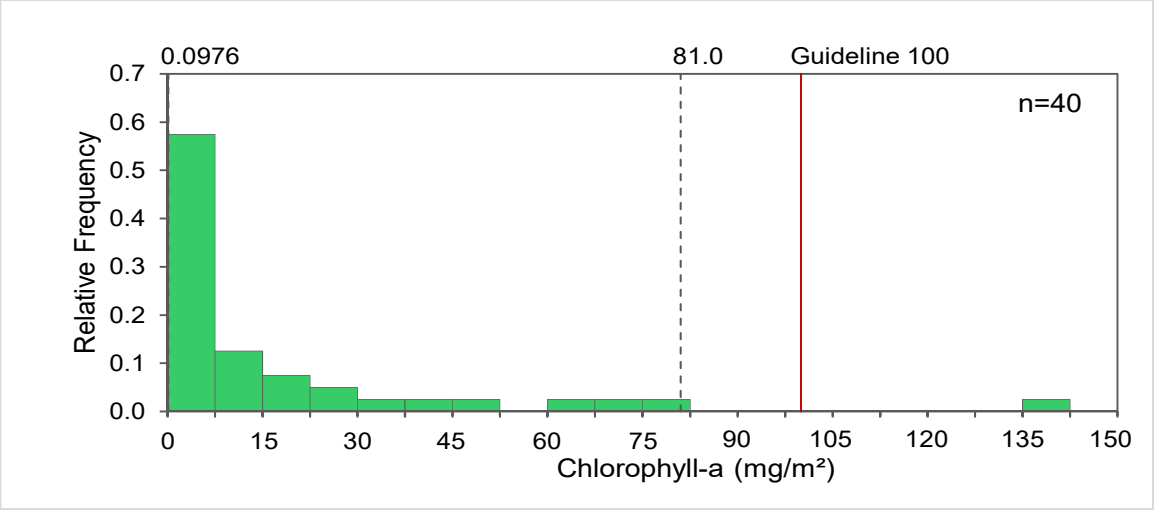
Concentration exceeds the Interim Sediment Quality Guideline (ISQG)/Lowest Effect Level (LEL) or single guideline (for selenium)

Concentration exceeds the Probable Effect Level (PEL)/Severe Effect Level (SEL)

[a] Total PAH guideline for sensitive sites (i.e., sites with sensitive aquatic habitat) based on the British Columbia Contaminated Sites Regulation B.C. Reg. 375/96 Schedule 9

[b] Total PAH guideline for typical sites (i.e., not a sensitive sediment site) based on the British Columbia Contaminated Sites Regulation B.C. Reg. 375/96 Schedule 9

APPENDIX F
PERIPHYTON PRODUCTIVITY AND SELENIUM



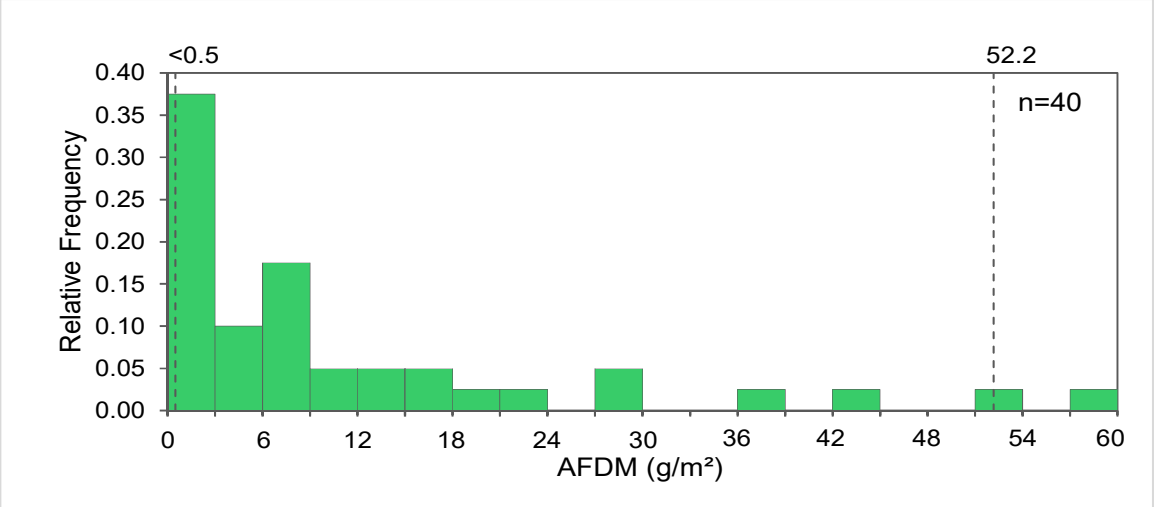


Figure F.1: Distribution of Reference Area Data (n = 40) for Periphyton Chlorophyll-a and Ash-Free-Dry-Mass (AFDM) collected in September, 2015 for all Reference Areas

Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles. No outliers were identified.

minnow environmental inc.
Figure F.2

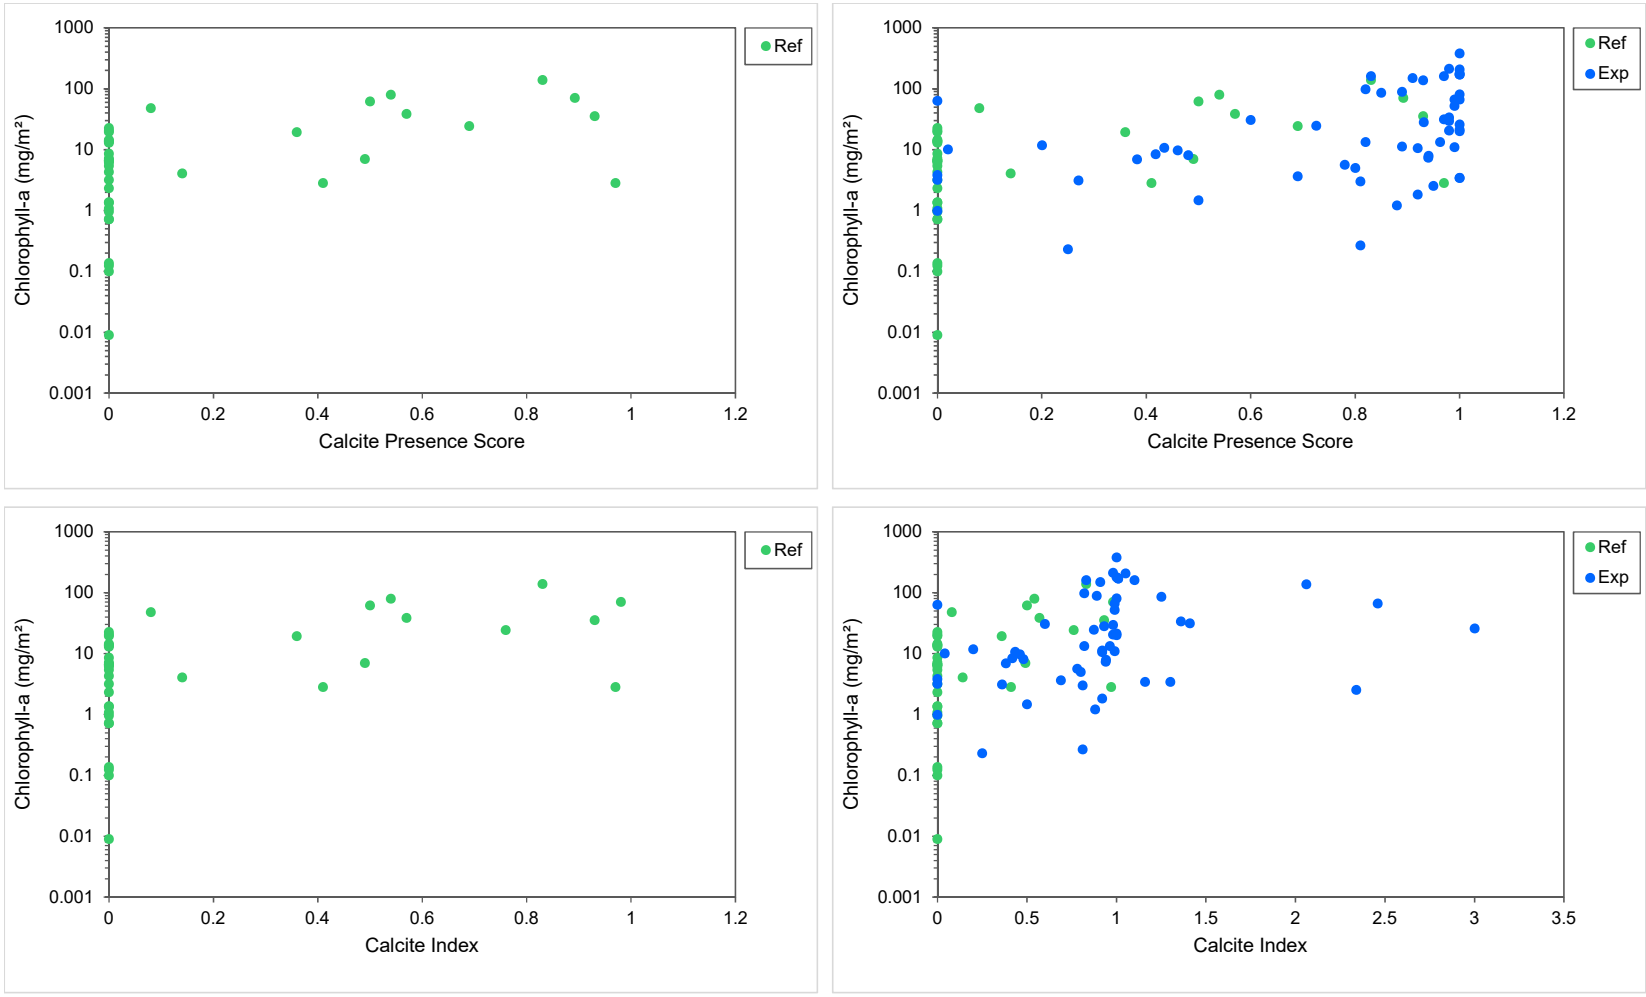

Figure F.3: Scatterplots of Periphyton Chlorophyll-a versus Calcite Presence Score and Calcite Index for Reference Areas (n = 40) (left) and Reference (n = 40) and Mine-exposed (n = 58*) Areas (Right)

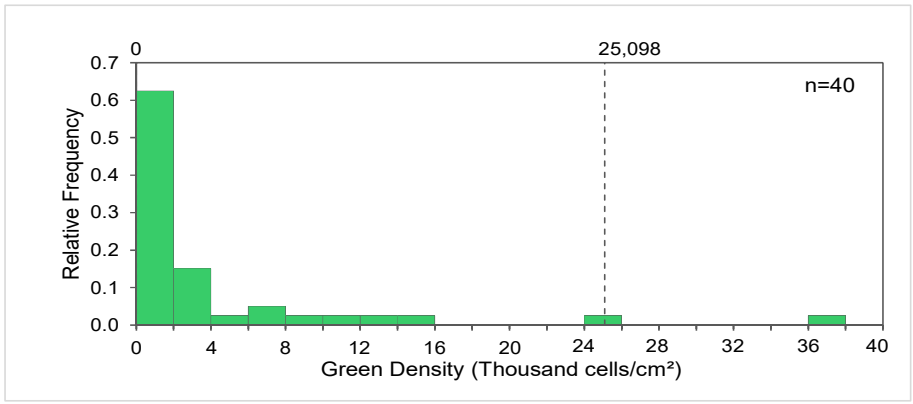
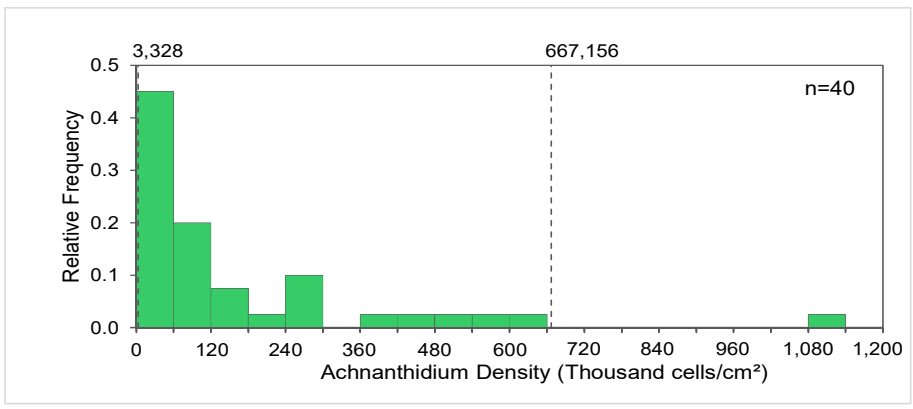
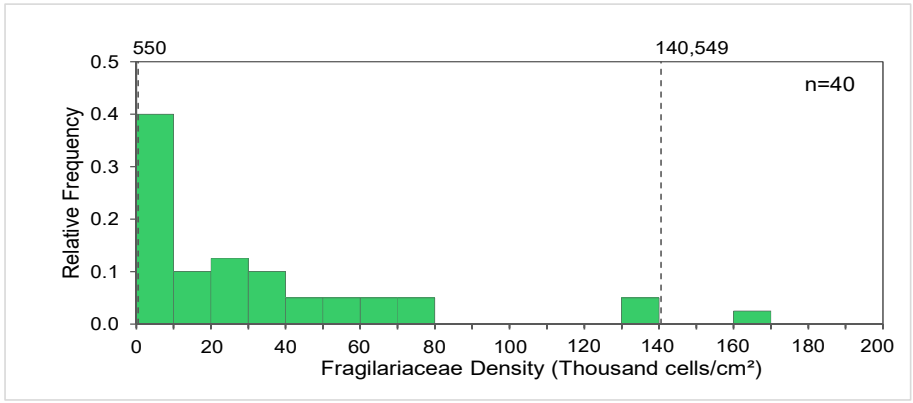
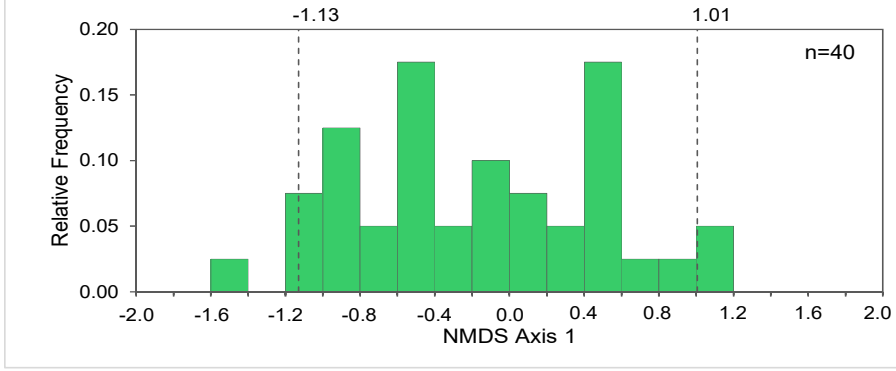
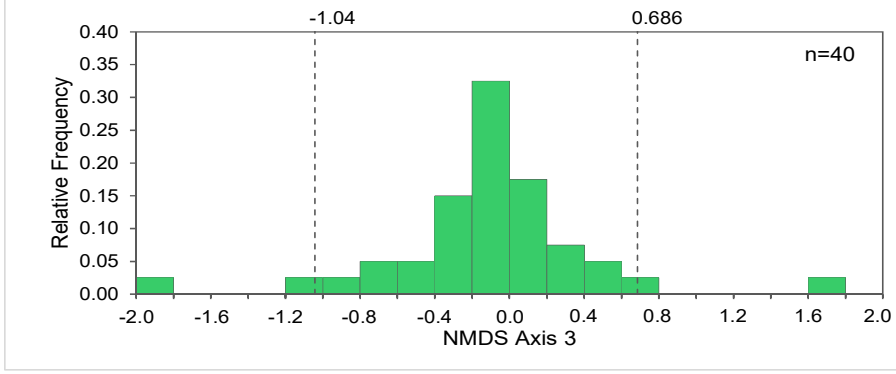
Notes: * Chlorophyll-a was not sampled at mine-exposed area NGD1.
Calcite presence score and calcite index were the two environmental variables that had Spearman correlation coefficients (r) with magnitude greater than 0.5 with chlorophyll-a











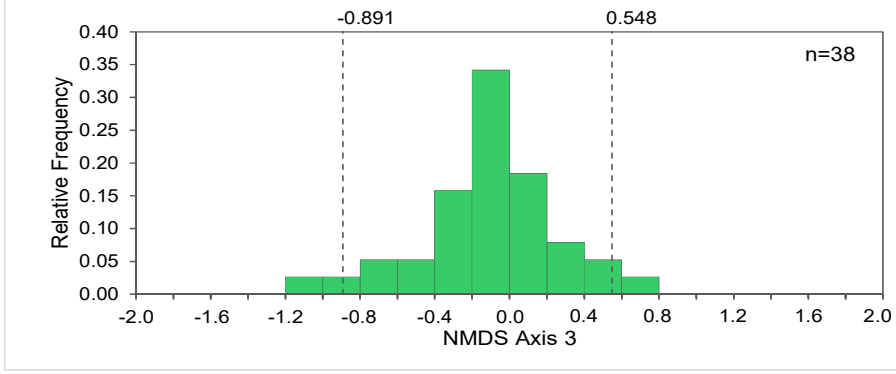


Figure F.4: Distribution of Reference Area Data (n = 40) for Periphyton Community Endpoints collected in 2015 for all Reference Areas (Left) and After Removal of Outliers (Right; when Applicable)

Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles.

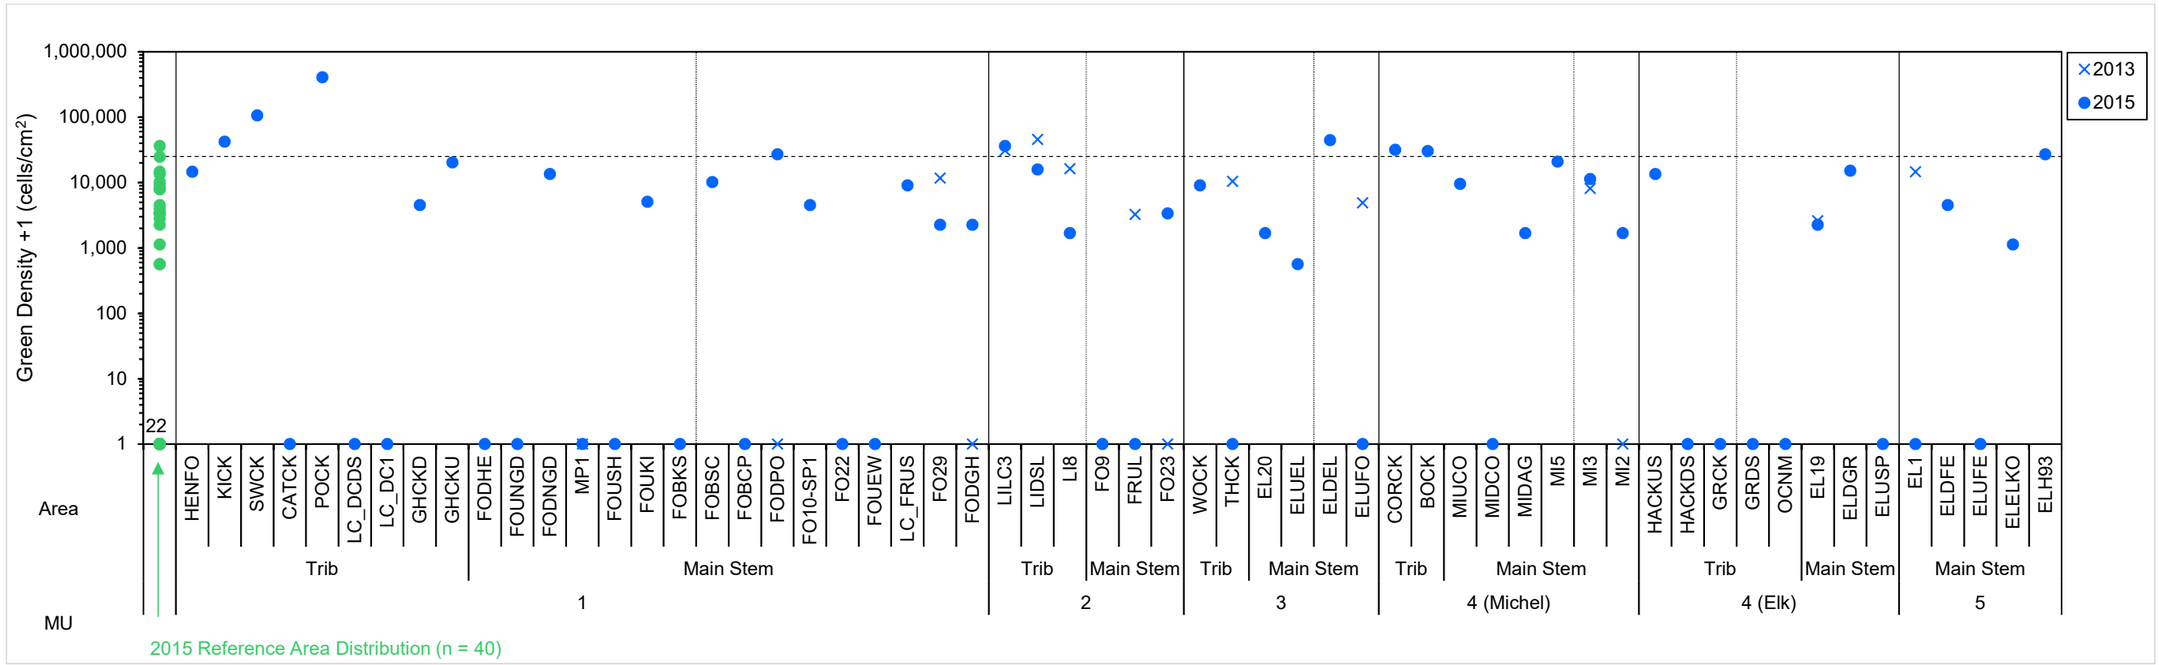

Figure F.5: Green Density for Mine-exposed Areas in Lotic Habitats, 2013 and 2015

Note: Dashed horiztonal lines represent the limits of the reference area normal range. The lower limit is a density of zero (plotted at Y = 1 in the plot)
A value of 1 has been added to the density to accommodate a log-transformation (zeros were present)

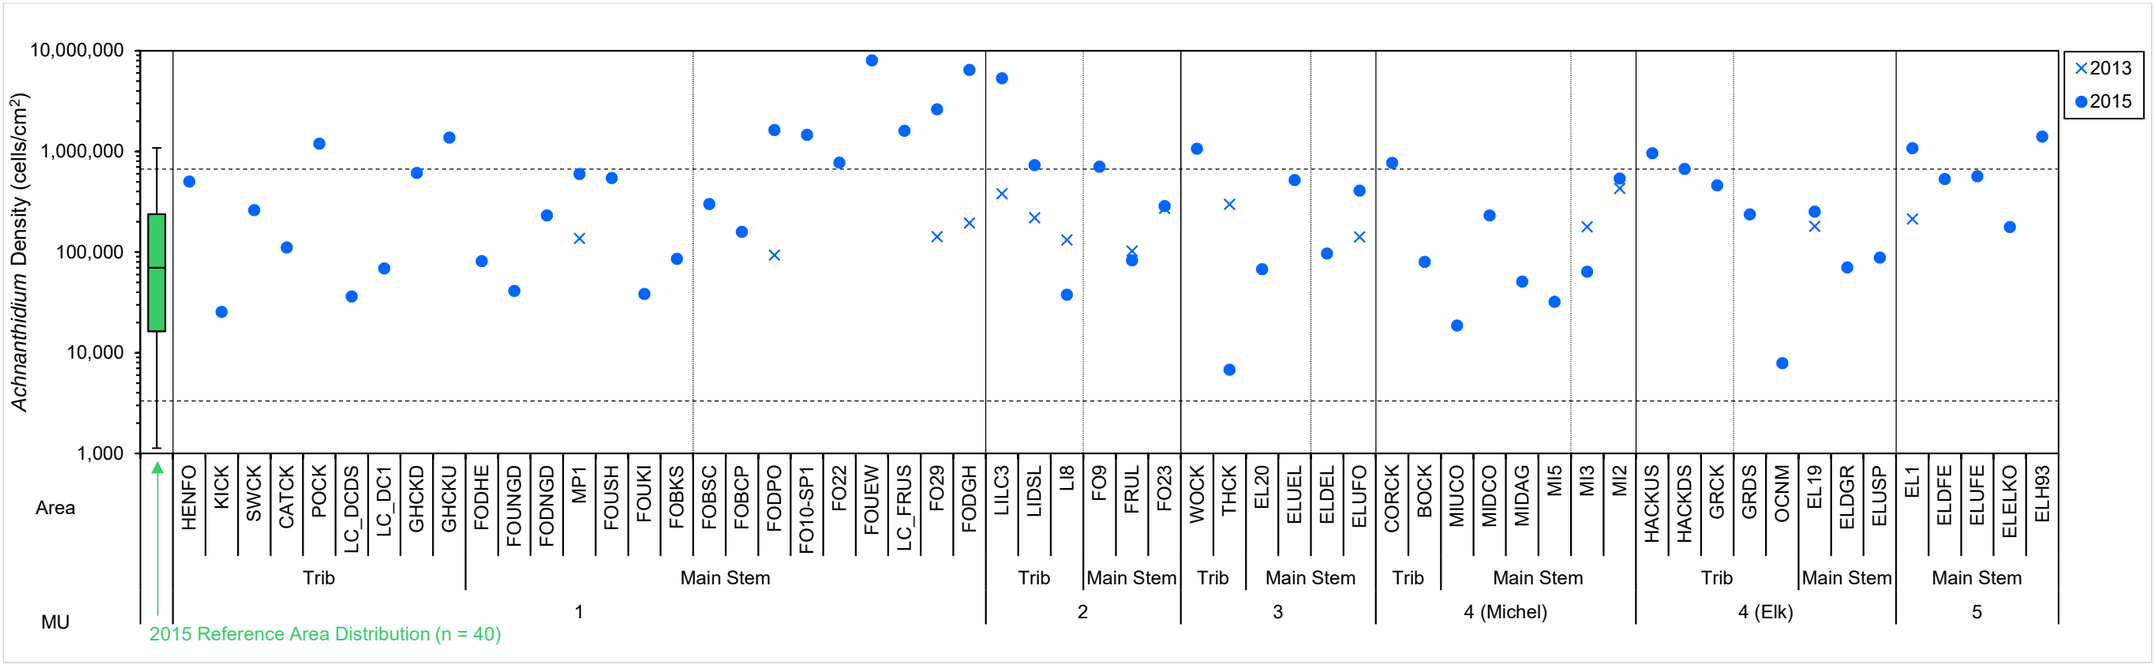

Figure F.6: *Achnanthidium* Density for Mine-exposed Areas in Lotic Habitats, 2013 and 2015

Note: Dashed horiztonal lines represent the limits of the reference area normal range.

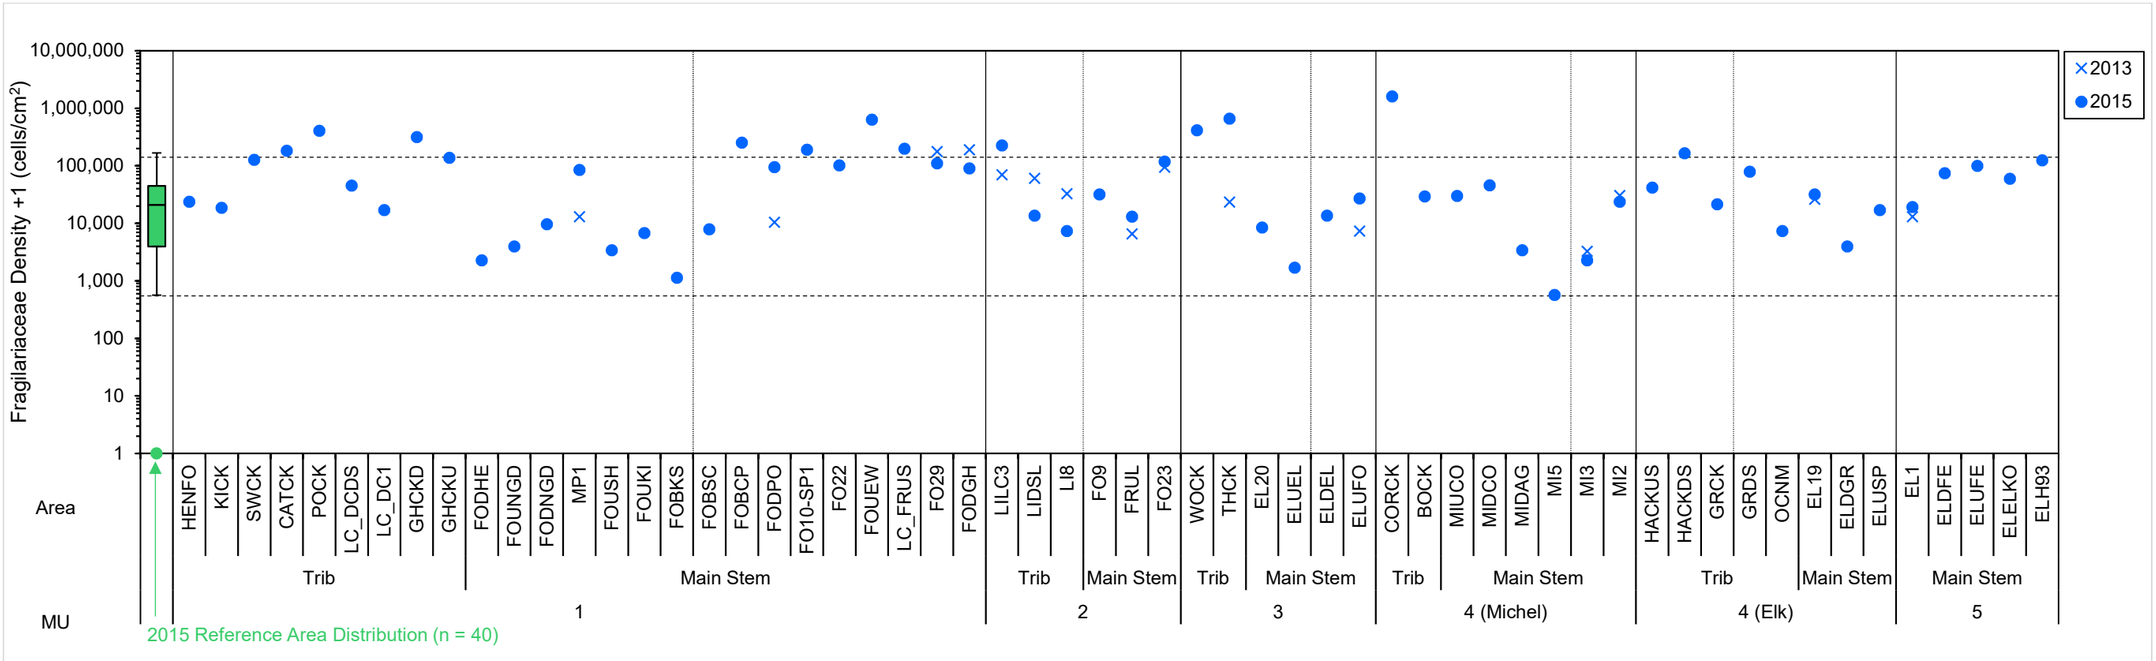

Figure F.7: Fragilariaceae Density for Mine-exposed Areas in Lotic Habitats, 2013 and 2015

Note: Dashed horiztonal lines represent the limits of the reference area normal range.
A value of 1 has been added to the density to accommodate a log-transformation (zeros were present)

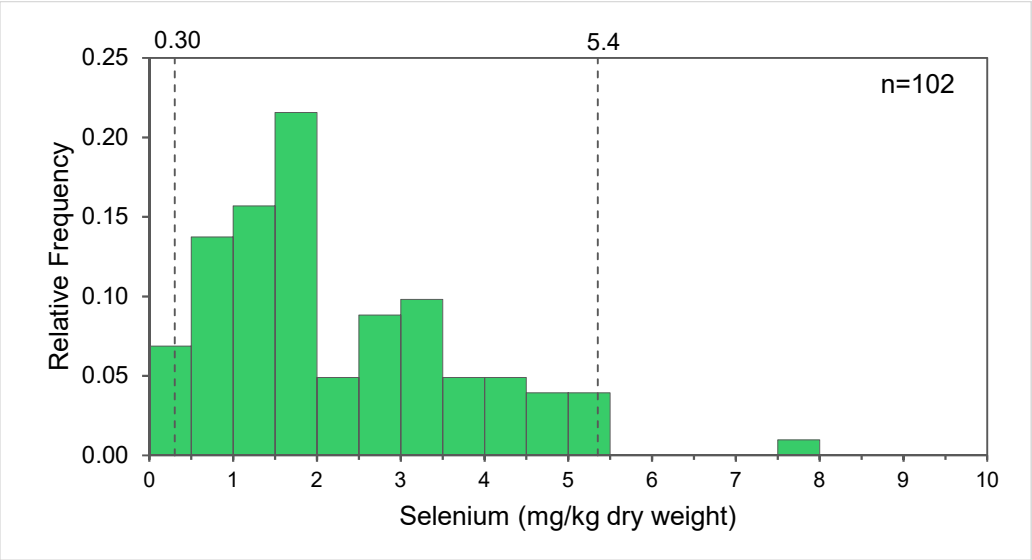

Figure F.8: Distribution of Reference Area Data for Tissue Selenium Concentrations for Periphyton in the Elk Valley, 1996 - 2015

Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles. No outliers were identified.

Chlorophyll-a values outside normal range

AFDM values outside normal range

Bold indicates result above the BC periphyton chlorophyll-a guideline of 100 mg/m^2.

[a] The laboratory reporting limit (LRL) was used to calculate the mean where measured concentrations were below the LRL.

r ≥ 0.6 or r ≤ -0.6.

P-value < 0.05.

Note: PCA Details in Appendix A. The mine-exposed area NGD1 was not sampled for periphyton in 2015.

[a] HQ - hazard quotient. Observed concentration divided by Level 1 effect benchmark defined in the Elk Valley Water Quality Plan (selenium, sulphate, nitrate, cadmium), the upper normal range limit defined by Minnow (2016; calcite index), or BC water quality guidelines (the other water quality variables), as applicable.

[b] Selenium, sulphate, nitrate.

Table F.10: Comparison of Reference Area Data Distributions for Periphyton Community Endpoints Based on Percentiles Derived from the 2015 (n = 40) Reference Area Results Before and After the Removal of Potential Outliers

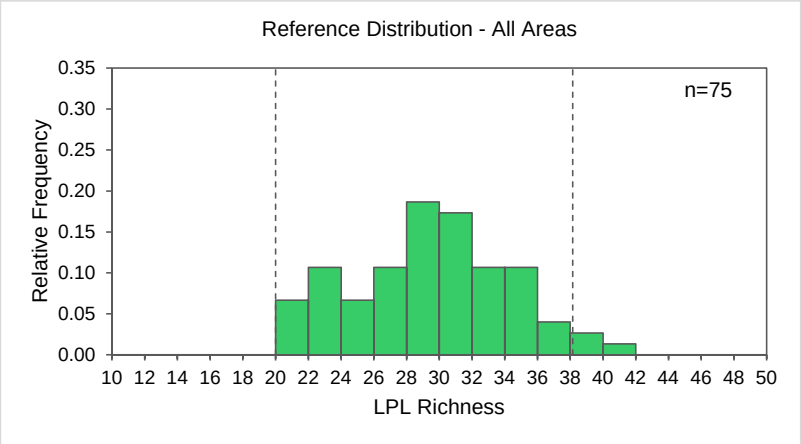
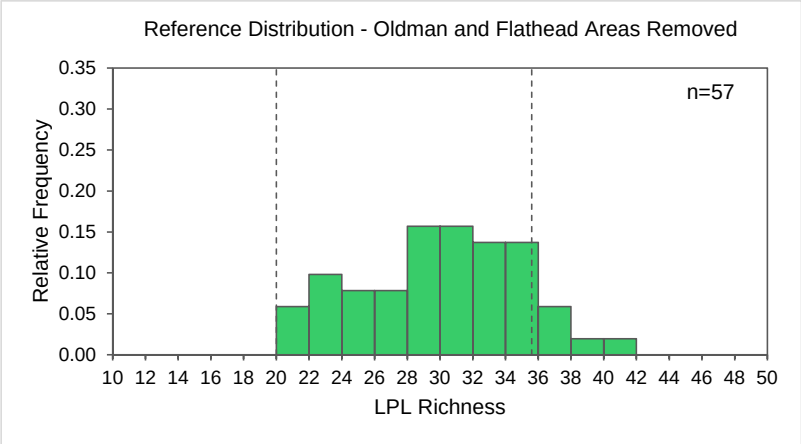
Figure G.1: Distribution of Reference Areas for Key Benthic Invertebrate Endpoints Sampled in 2012 and 2015 with Normal Ranges (2.5th and 97.5th Percentiles) Shown as Dashed Vertical Lines





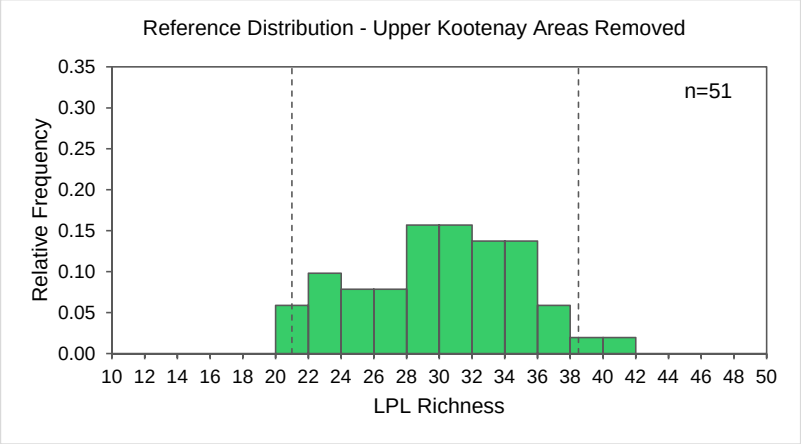


Figure G.1: Distribution of Reference Areas for Key Benthic Invertebrate Endpoints Sampled in 2012 and 2015 with Normal Ranges (2.5th and 97.5th Percentiles) Shown as Dashed Vertical Lines

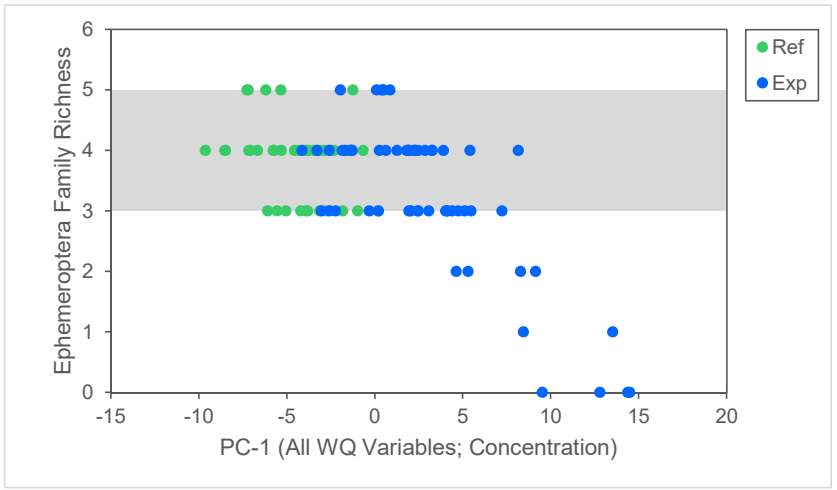
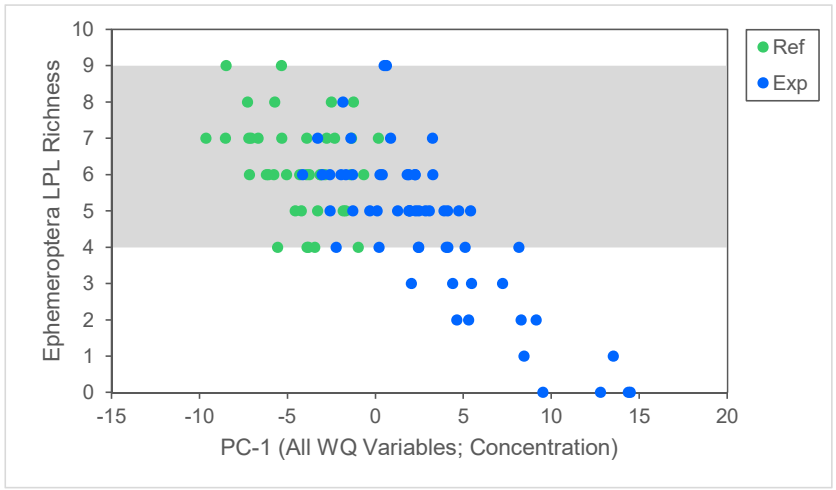
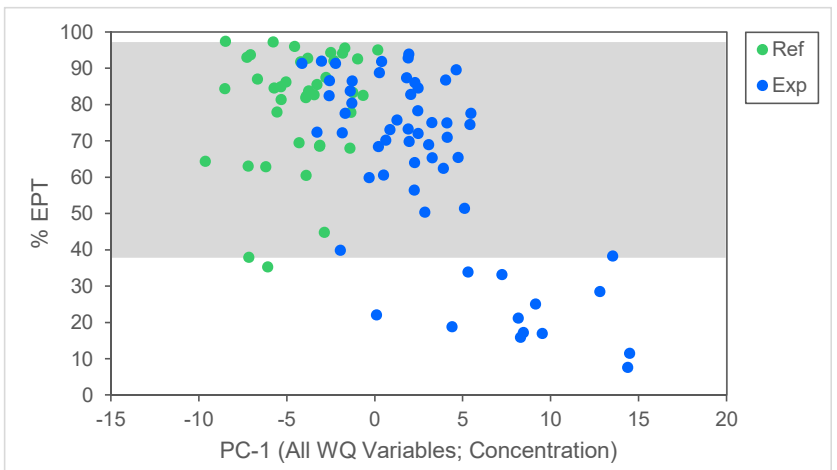
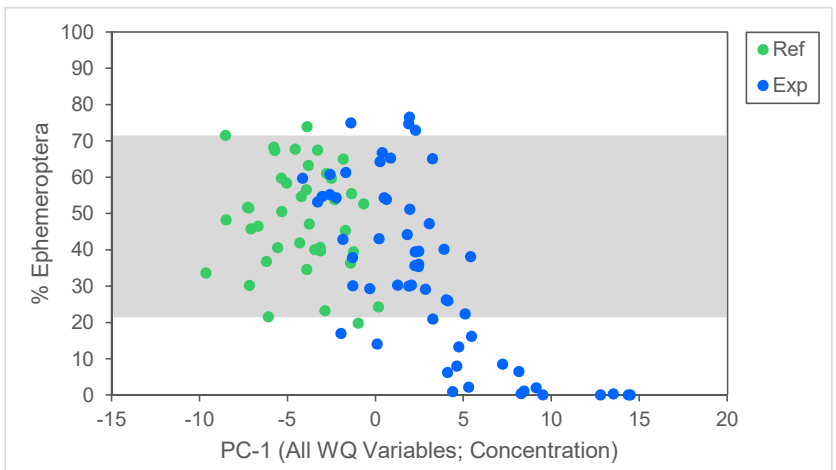
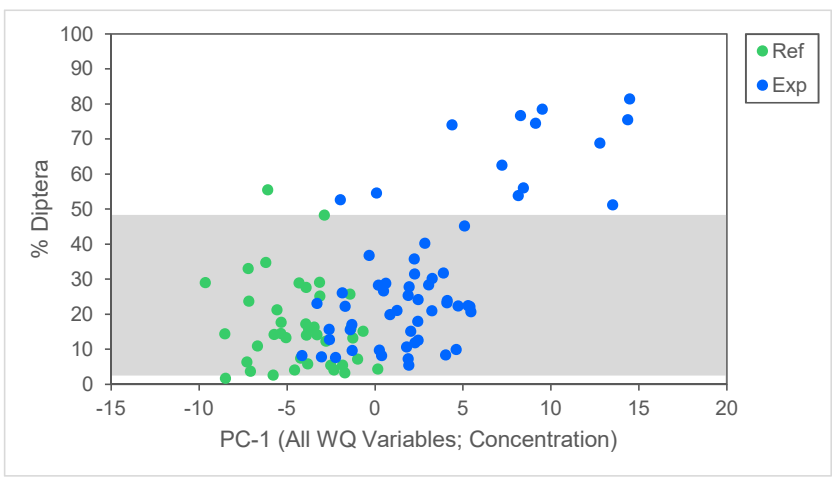
Notes: NMDS Axis 1 scores from an NMDS conducted on relative abundances (fourth-root transformed) using the family-level of taxonomy

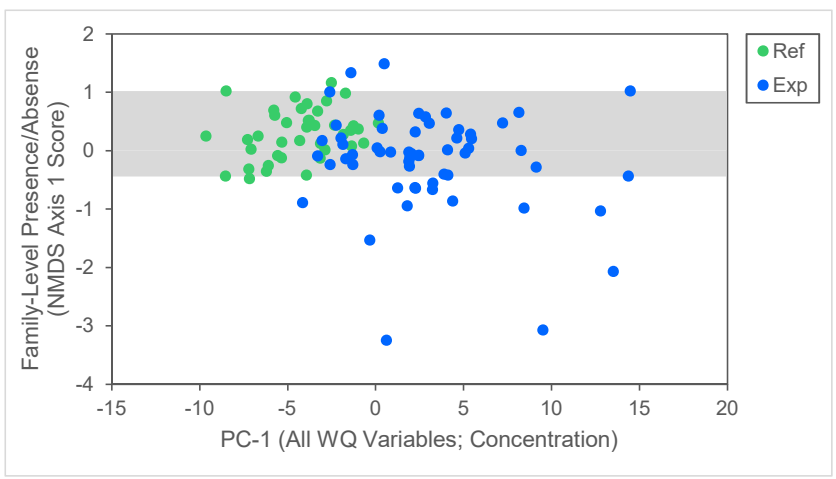


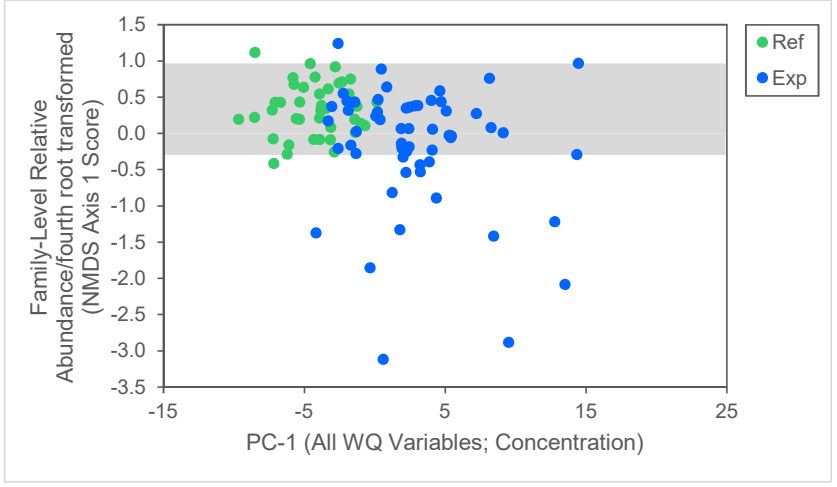












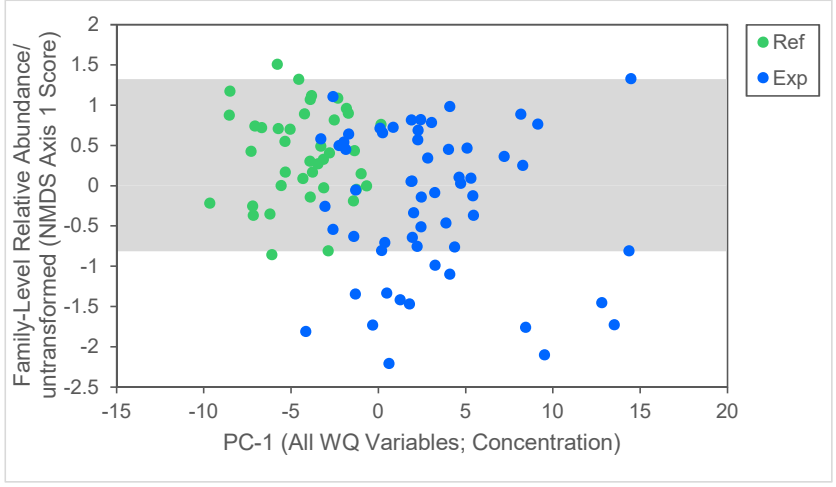


Figure G.2: Plots of Benthic Invertebrate Community Endpoints with Pearson's Correlation Coefficient (r) Greater than 0.6 or Less than -0.6 for Reference (n = 40) and Mine-exposed (n = 59) Areas to PC-1 for Concentrations of All Water Quality Variables (Most Plots) or For HQs of Key Mine-related Variables (Last Plot), September 2015

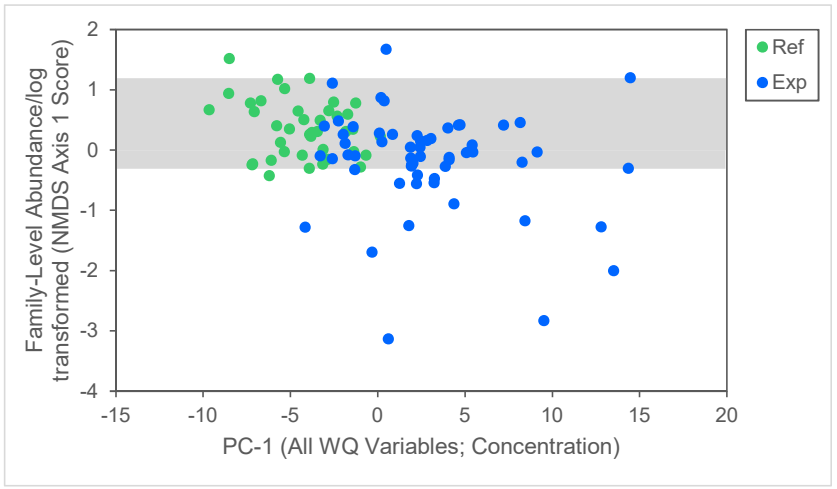
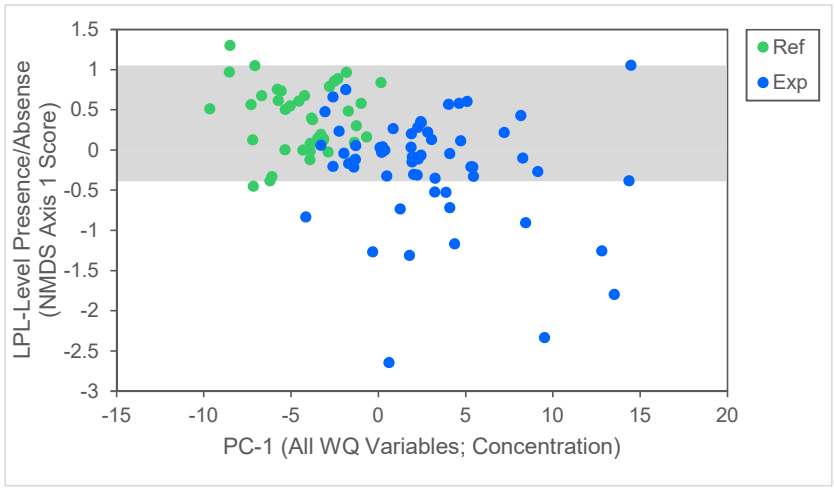
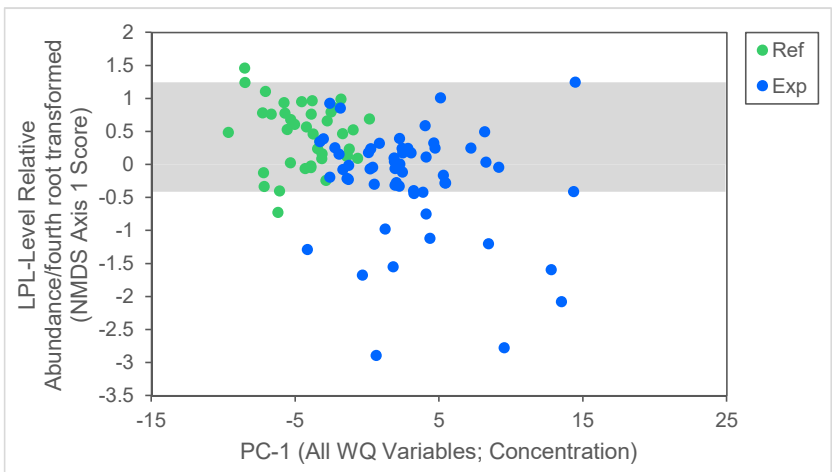
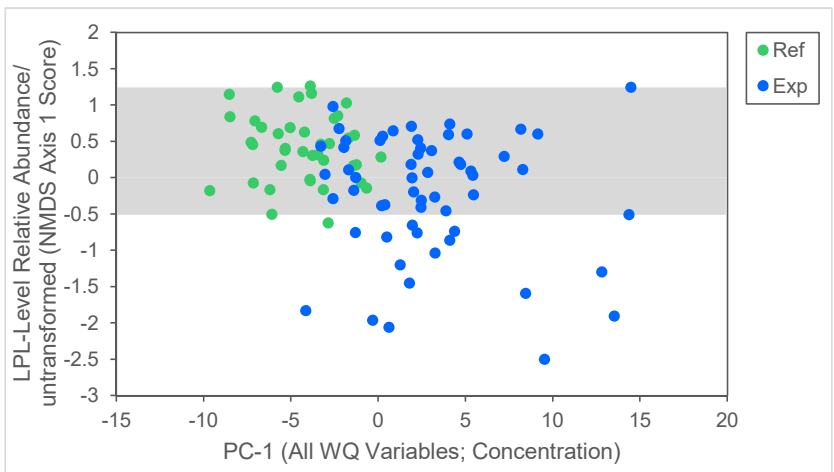
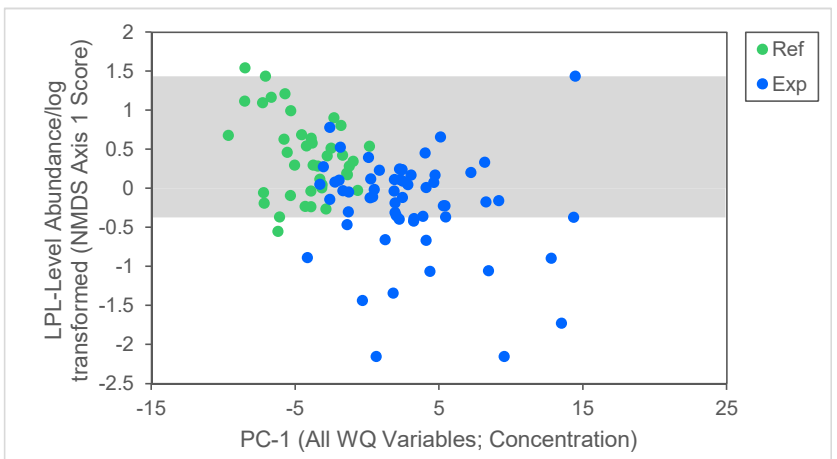
Notes: key WQ variables = calcite index, nitrate, sulphate, and total selenium; HQs calculated using level 1 effect benchmarks; gray shading represents the normal range defined as the 2.5th and 97.5th percentiles of the distribution of reference area values

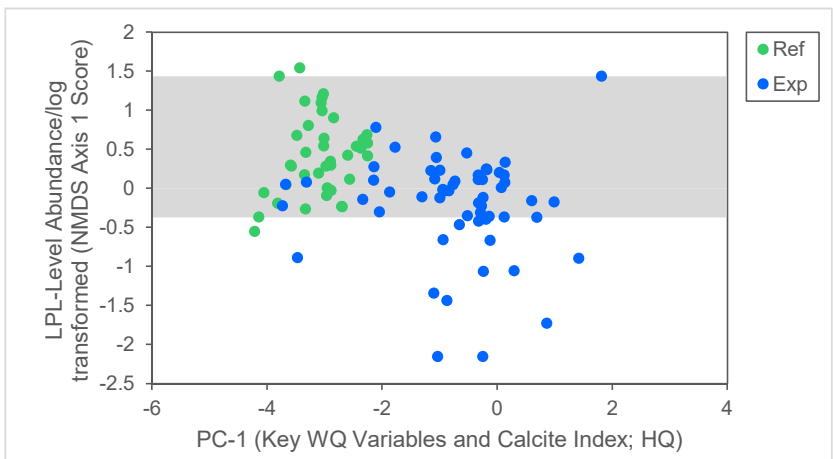


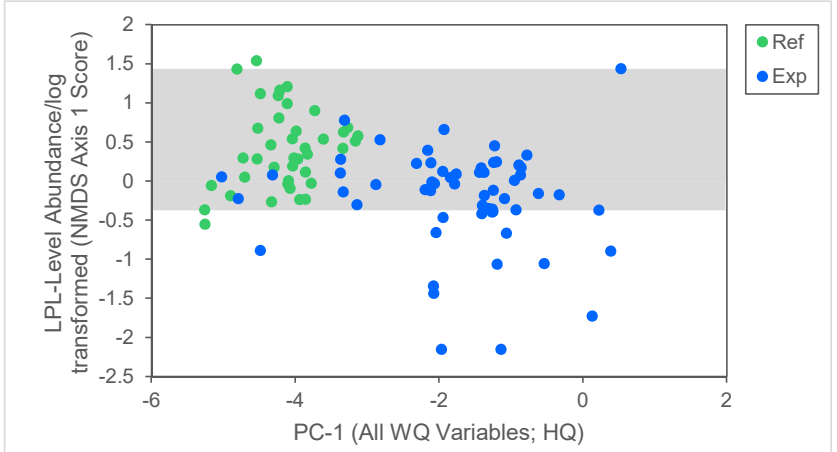












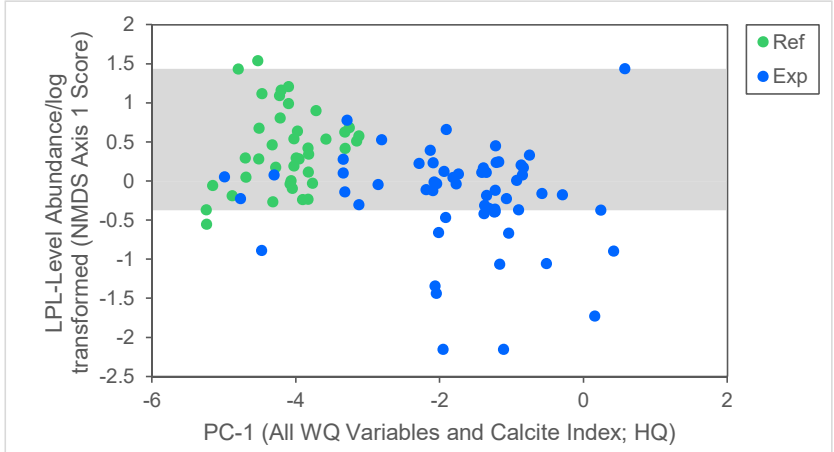


Figure G.2: Plots of Benthic Invertebrate Community Endpoints with Pearson's Correlation Coefficient (r) Greater than 0.6 or Less than -0.6 for Reference (n = 40) and Mine-exposed (n = 59) Areas to PC-1 for Concentrations of All Water Quality Variables (Most Plots) or For HQs of Key Mine-related Variables (Last Plot), September 2015

Notes: key WQ variables = calcite index, nitrate, sulphate, and total selenium; HQs calculated using level 1 effect benchmarks; gray shading represents the normal range defined as the 2.5th and 97.5th percentiles of the distribution of reference area values

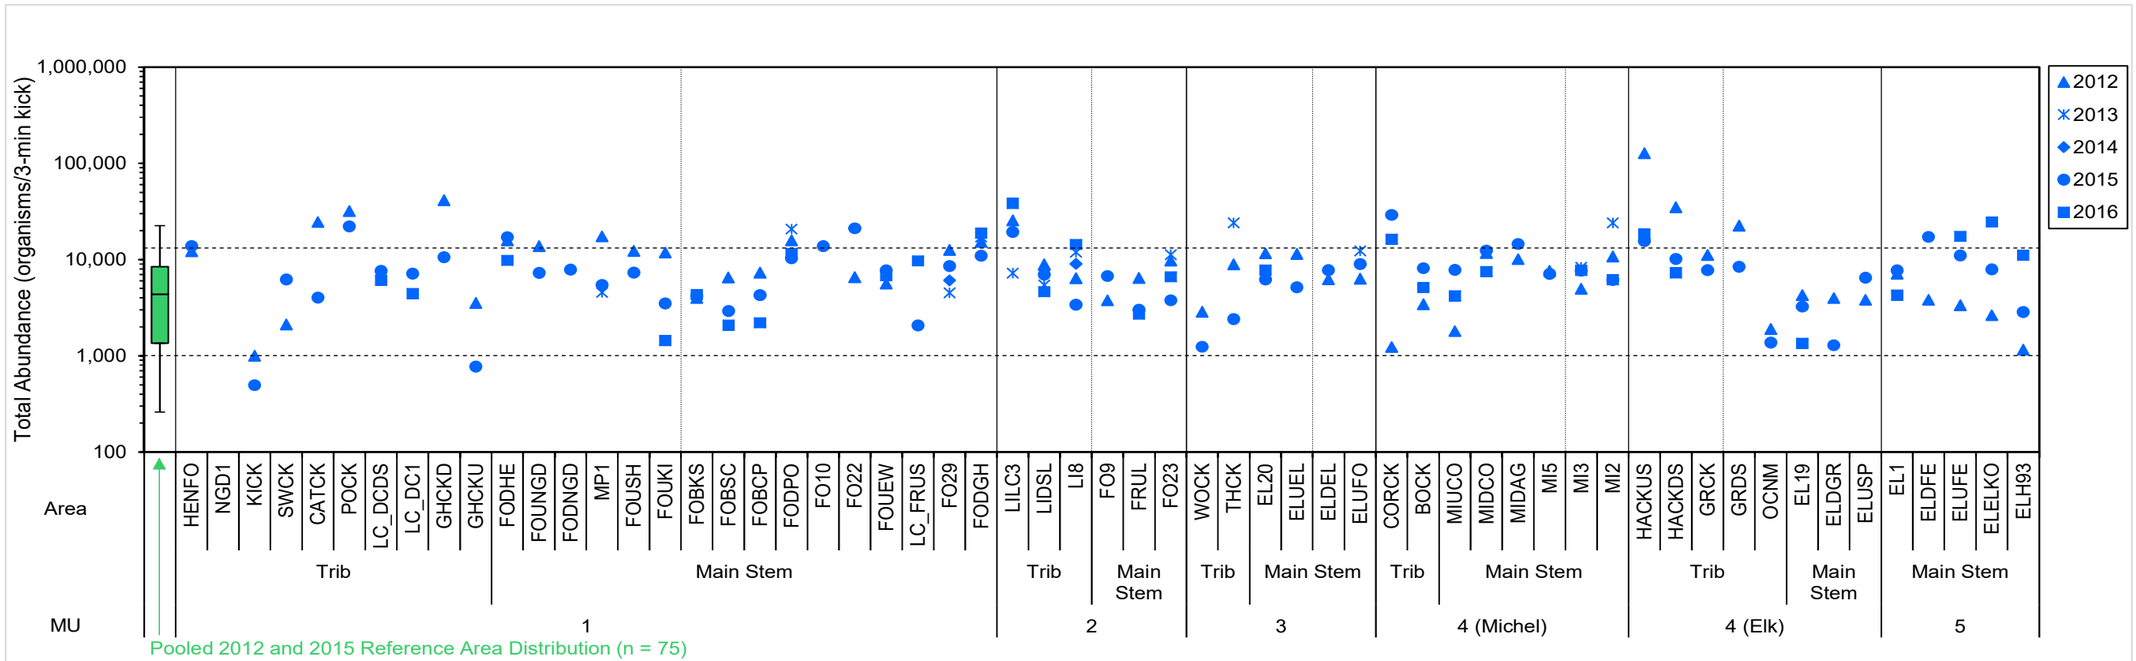

Figure G.3: **Total Benthic Invertebrate Abundance from 3-minute Kick Samples Collected in Lotic Habitats, 2012 - 2016**

Note: Dashed horiztonal lines represent the limits of the reference area normal range. The reference area distribution that is plotted in the boxplot includes all reference areas

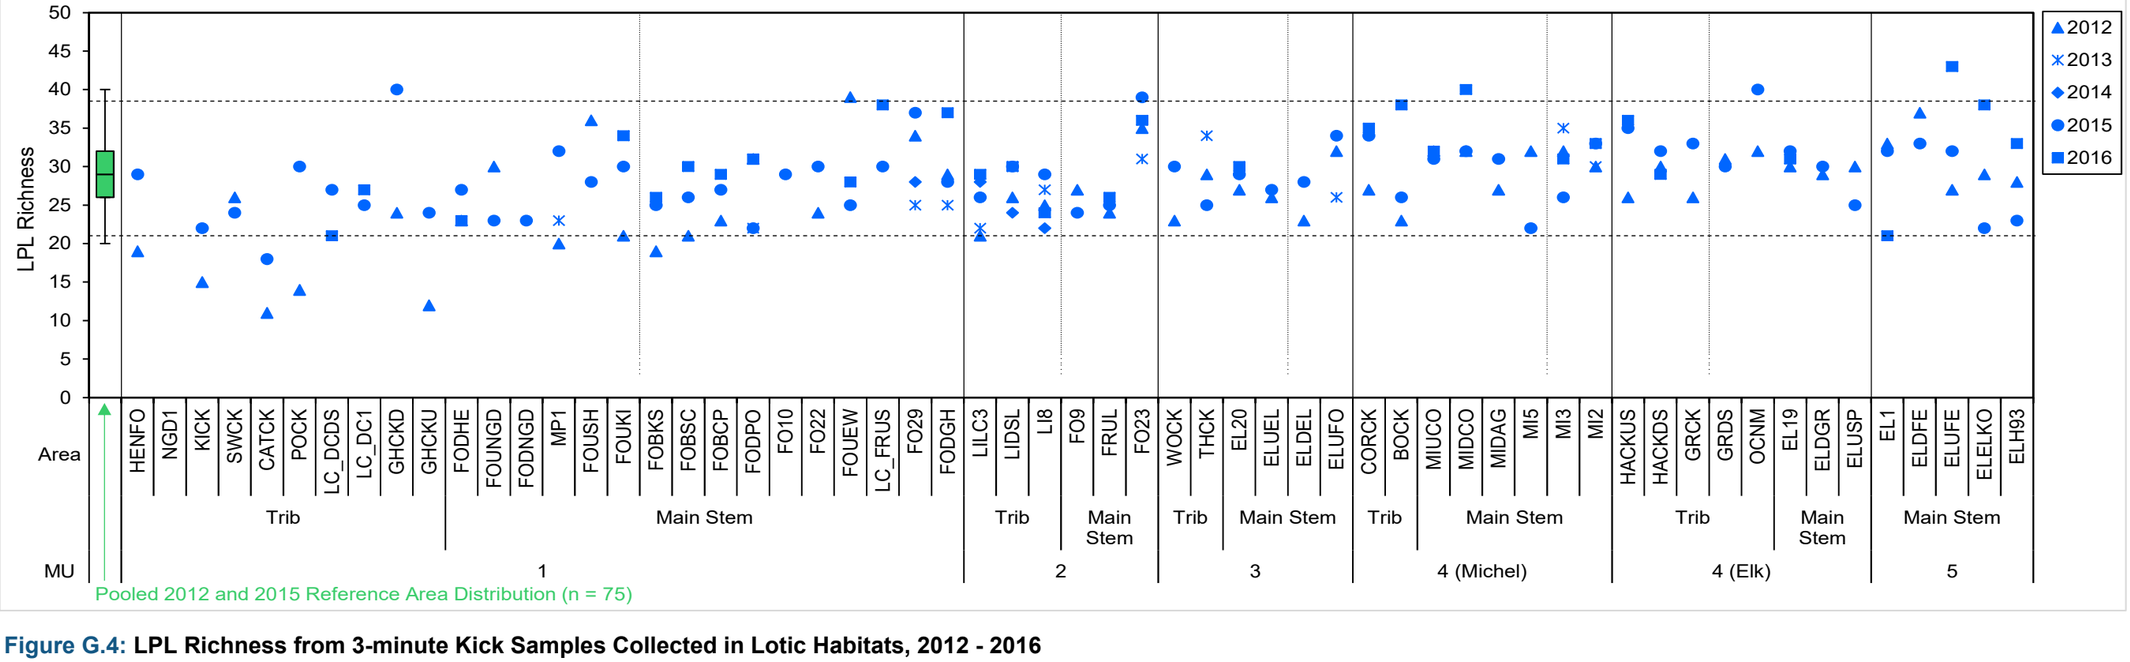

Figure G.4: LPL Richness from 3-minute Kick Samples Collected in Lotic Habitats, 2012 - 2016

Note: Dashed horiztonal lines represent the limits of the reference area normal range. The reference area distribution that is plotted in the boxplot includes all reference areas

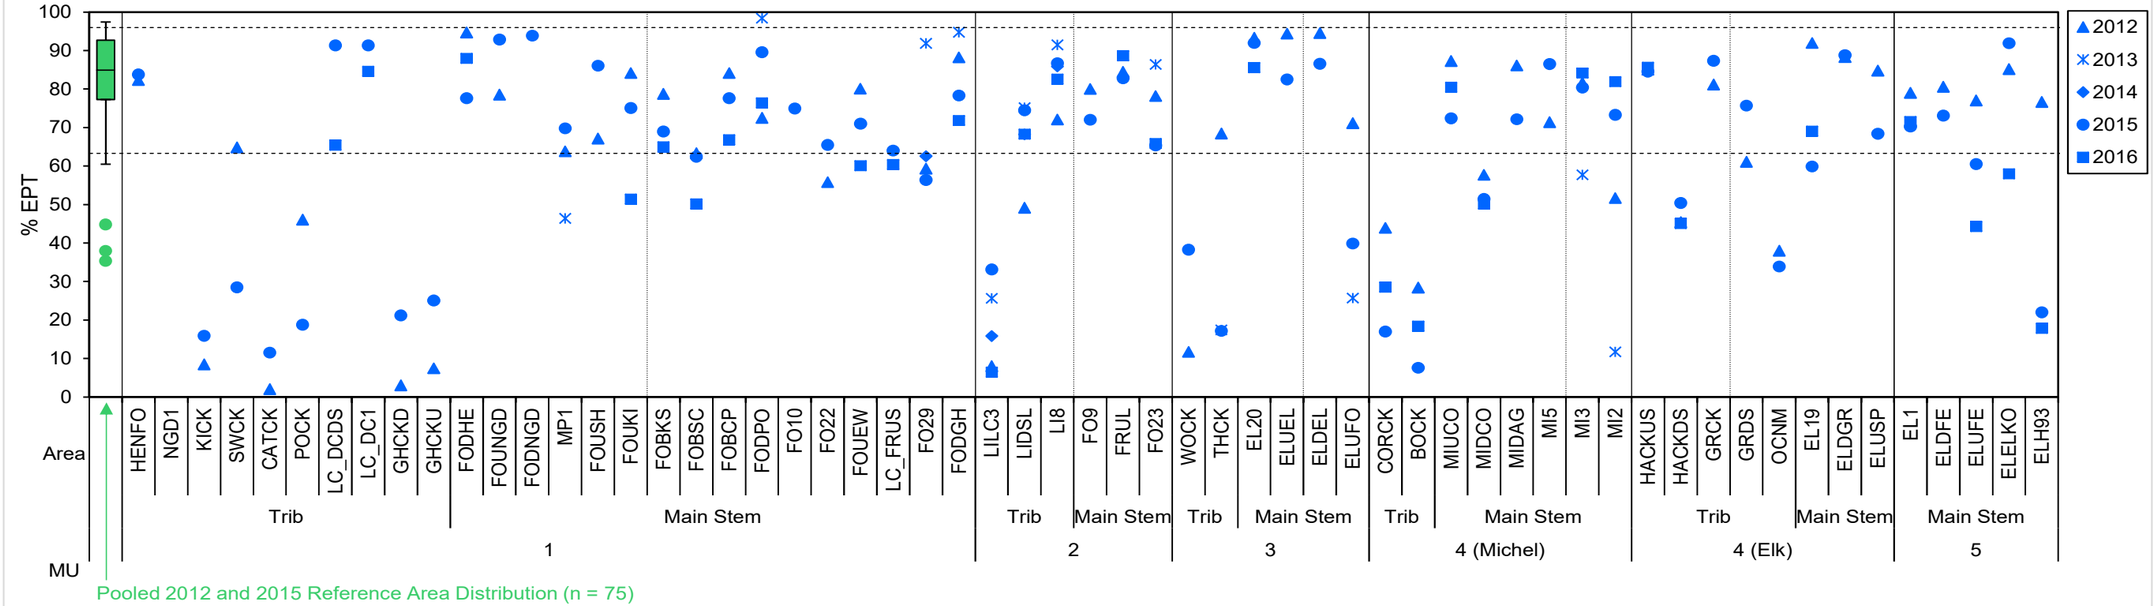

Figure G.5: % EPT from 3-minute Kick Samples Collected in Lotic Habitats, 2012 - 2016

Note: Dashed horiztonal lines represent the limits of the reference area normal range. The reference area distribution that is plotted in the boxplot includes all reference areas

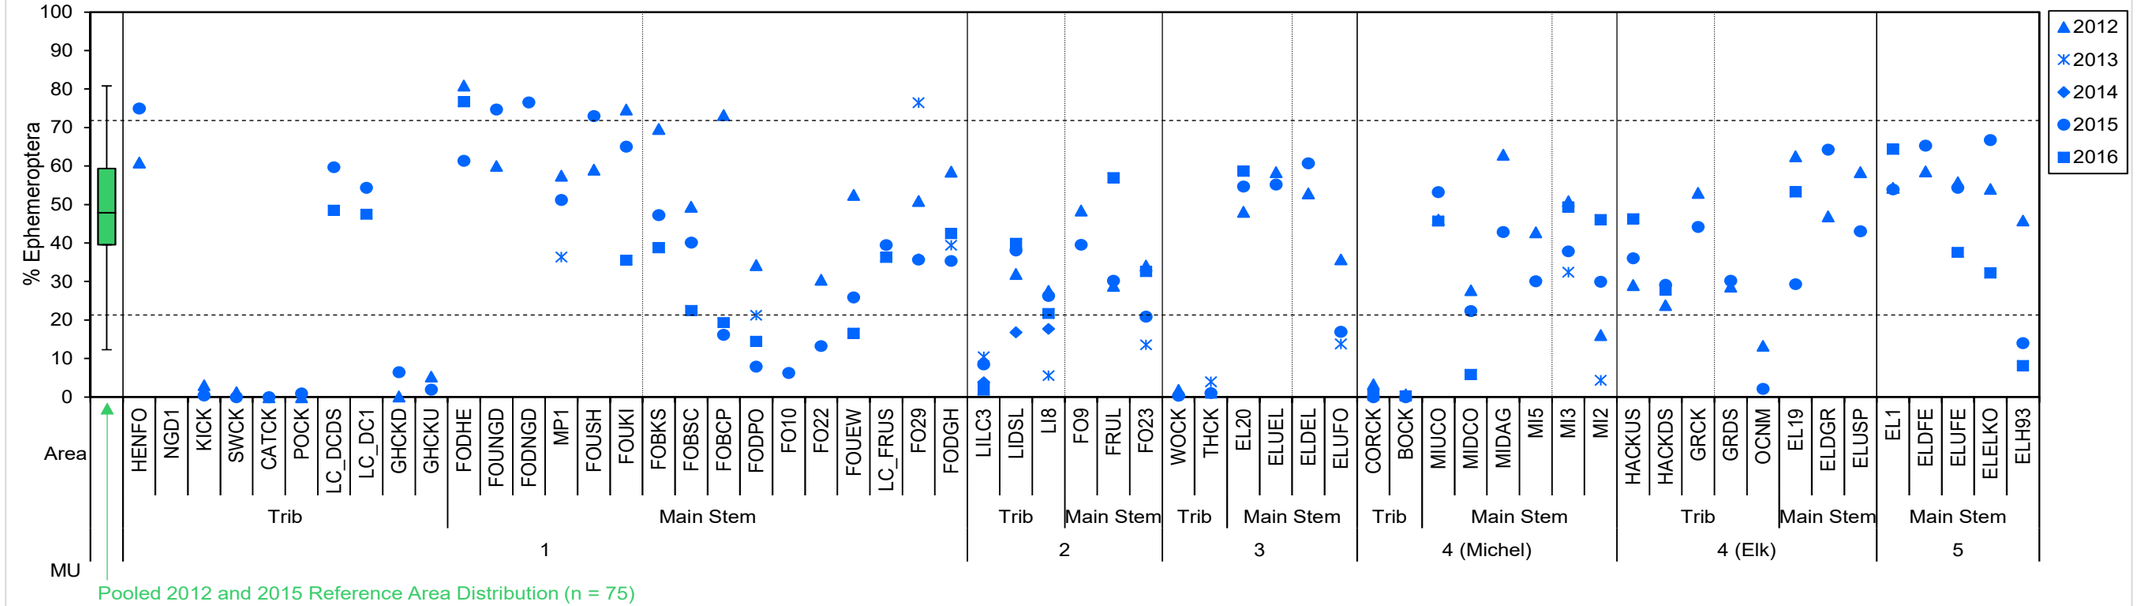

Figure G.6: % Ephemeroptera from 3-minute Kick Samples Collected in Lotic Habitats, 2012 - 2016

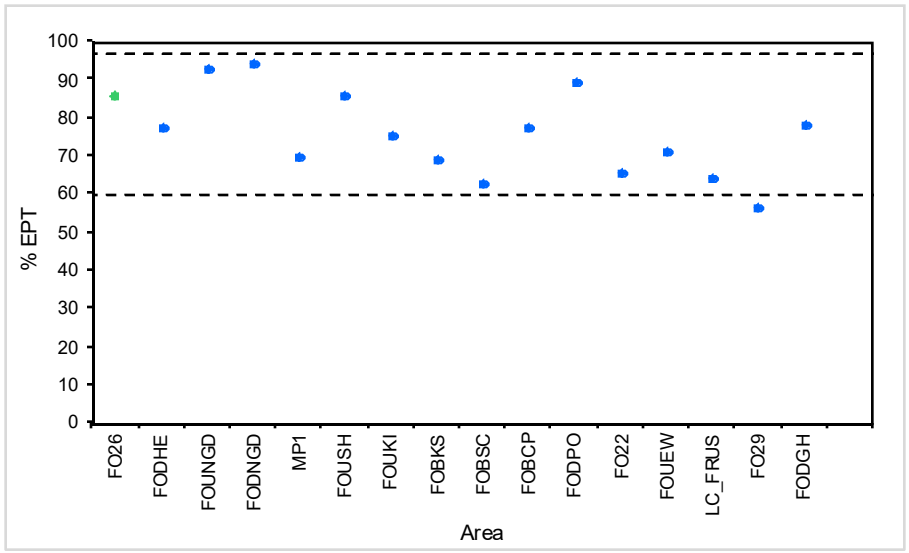
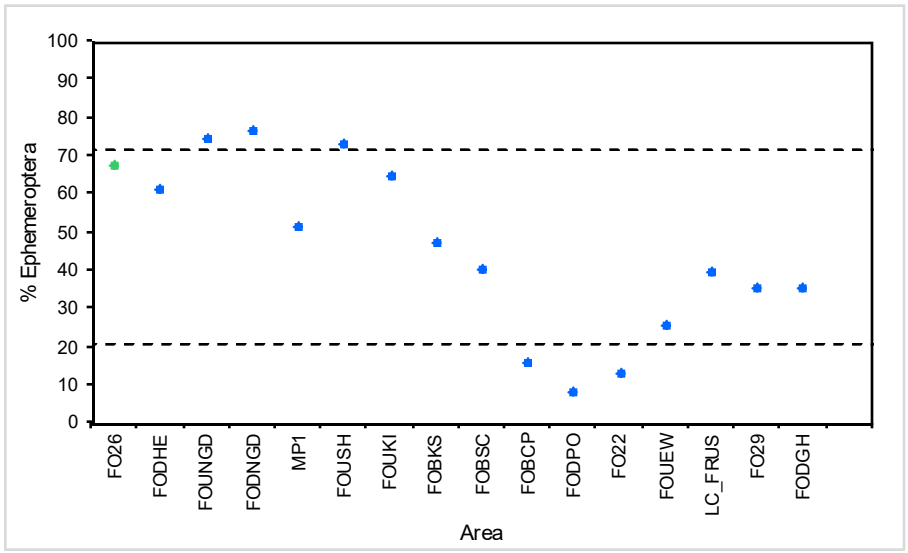
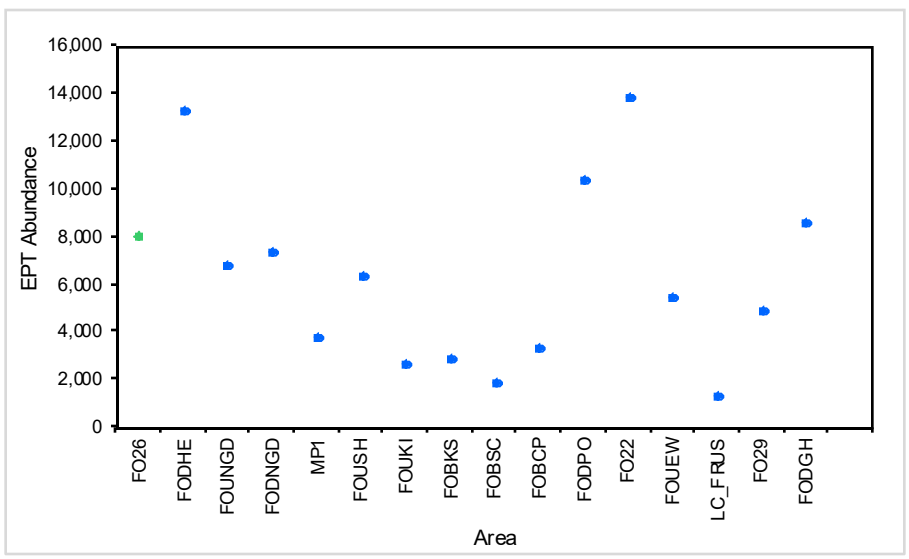
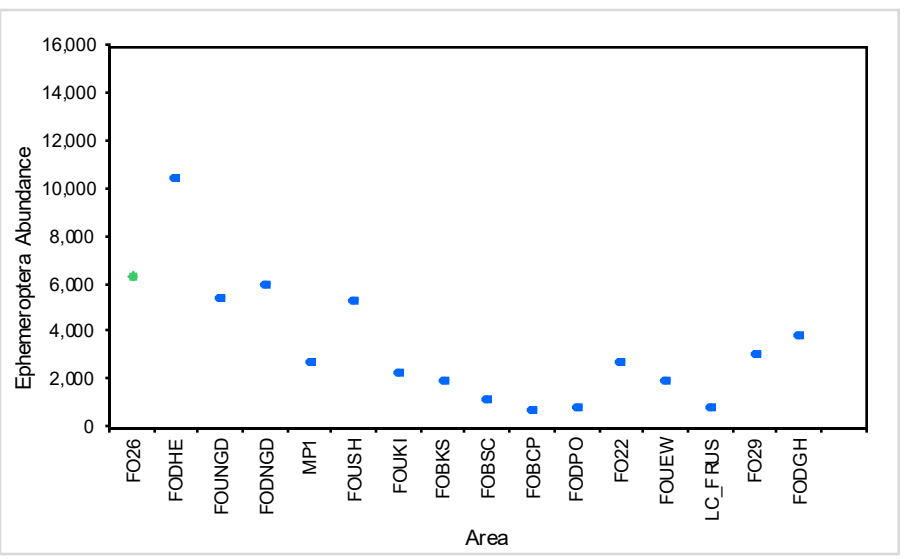
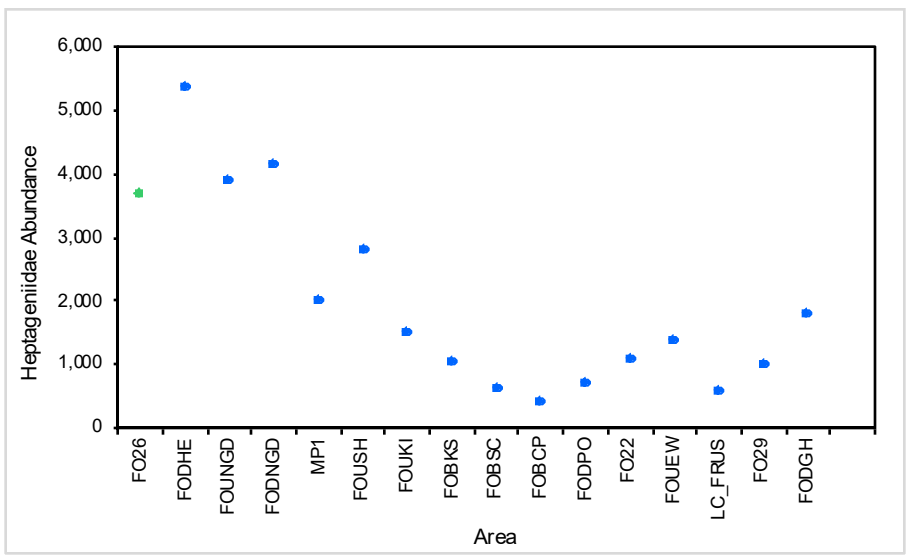
Note: Dashed horiztonal lines represent the limits of the reference area normal range. The reference area distribution that is plotted in the boxplot includes all reference areas

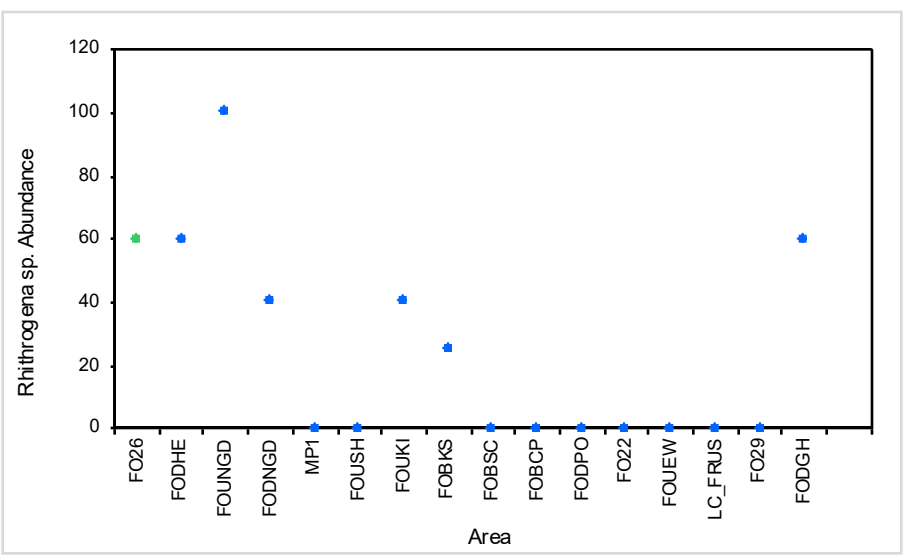


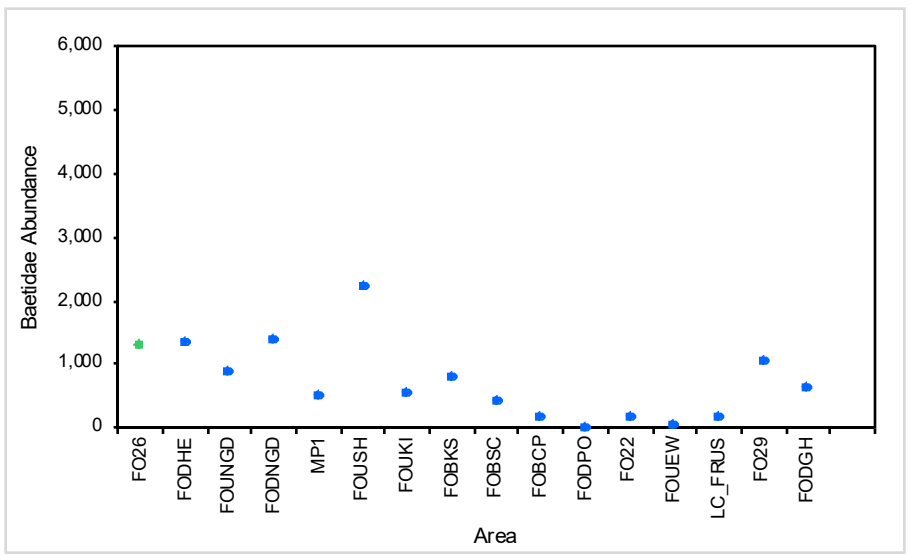


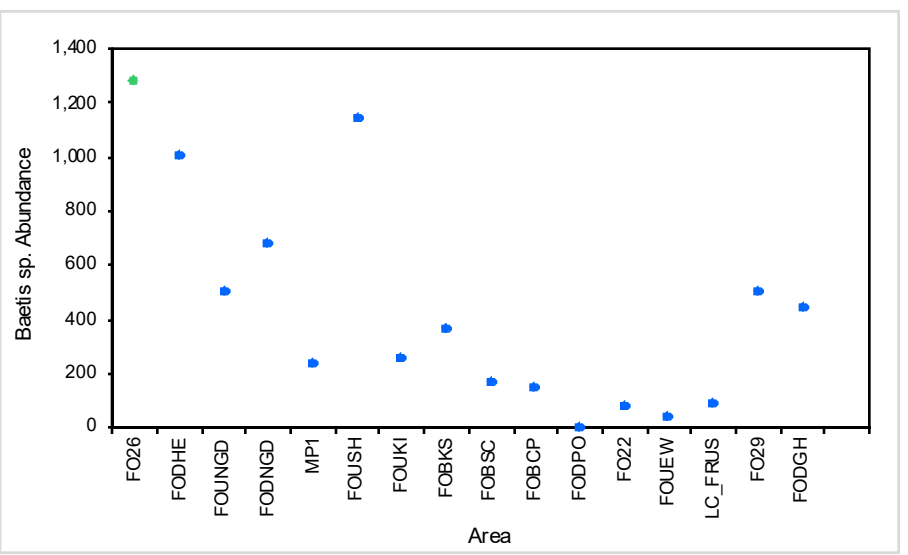


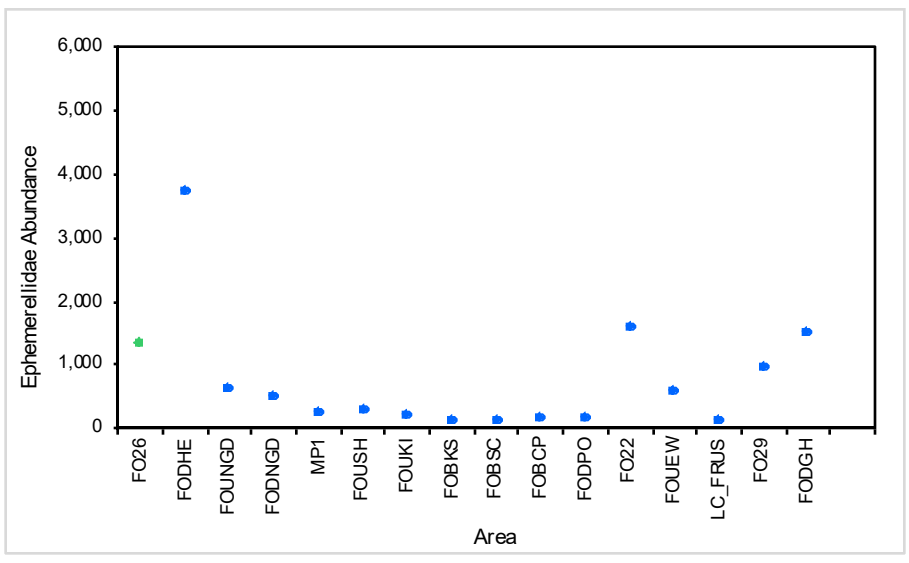












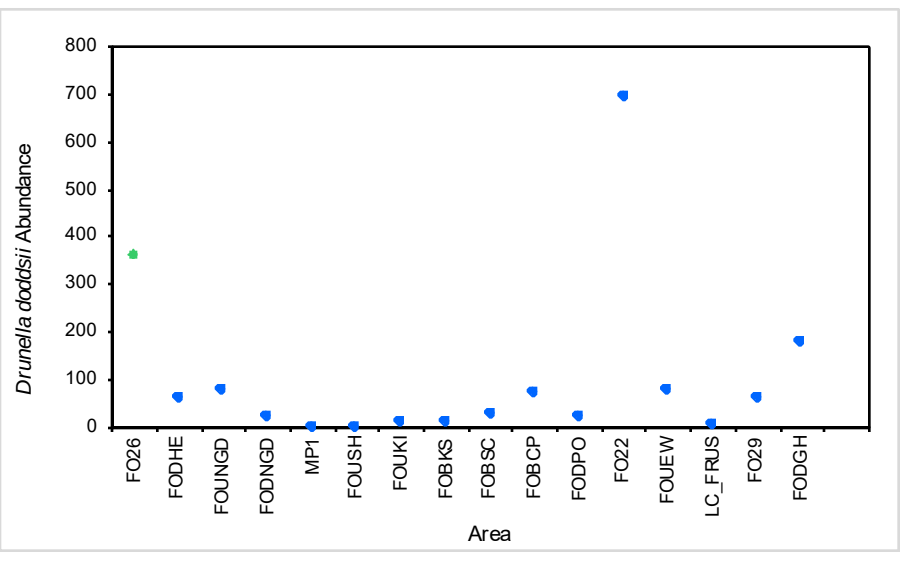


Figure G.7: EPT and Ephemeroptera (% and Abundance), and Ephemeroptera Taxa Abundance in the Upper Fording River, 2015

Note: Dashed horizontal lines represent the limits of the reference area normal range. The reference area distribution that is plotted in the boxplot includes all reference areas prior to the removal of outliers.

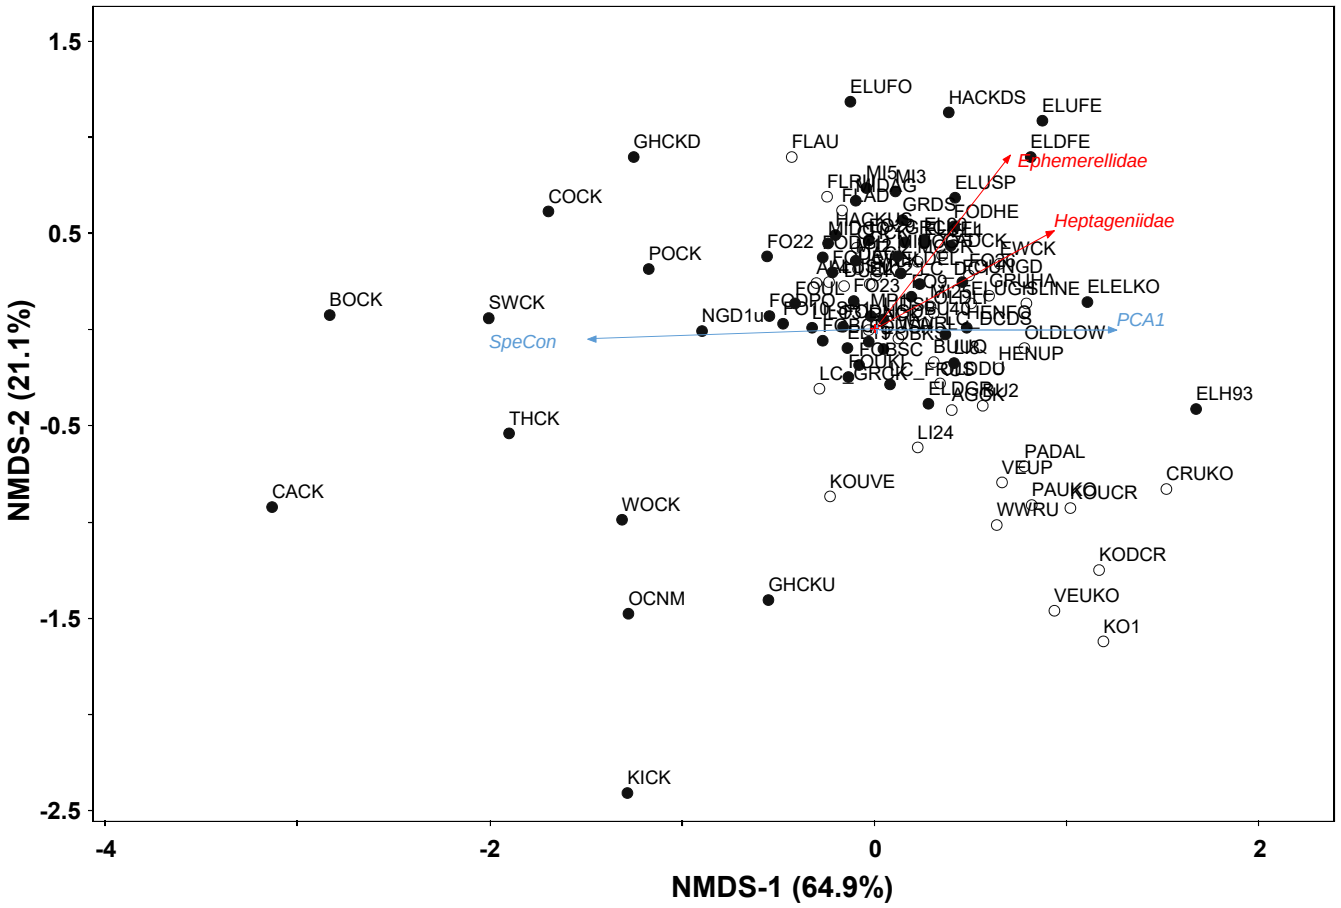

Figure G.8: Nonmetric Multidimensional Scaling Scatter Plot of Benthic Invertebrate Community Structure at 40 Reference Areas (Open Circles) and 59 Mine-exposed Areas (Closed Circles; Log_{10} Transformed Abundance Matrix, Family Level of Taxonomy)

Notes: Direct correlation vectors are displayed for family having an absolute Pearson's correlation coefficient (r) greater than 0.6 with NMDS area axis scores. Indirect correlation of environmental variables resulting in an absolute r value cutoff of 0.6 are shown. Vector length is proportional to correlation strength. A stable 2-dimensional solution was found with stress of 19.24.

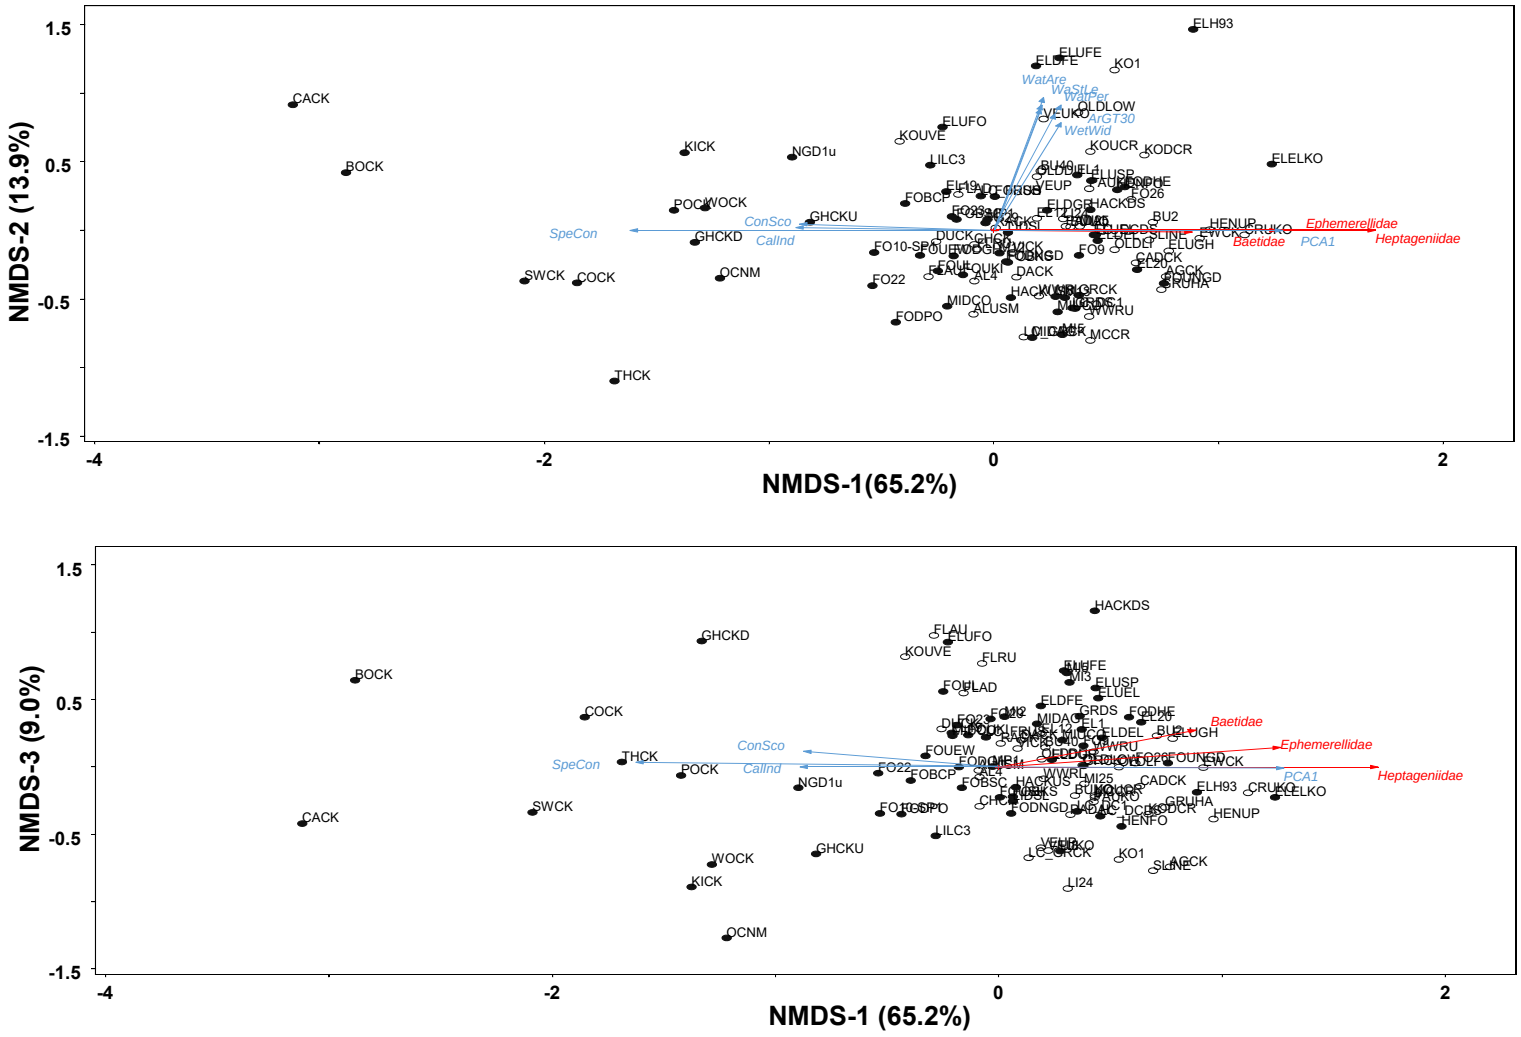

Figure G.9: Nonmetric Multidimensional Scaling Scatter Plot of Benthic Invertebrate Community Structure at 40 Reference Areas (Open Circles) and 59 Mine-exposed Areas (Closed Circles; Fourth Root Transformed Proportional Matrix, Family Level of Taxonomy)

Notes: Direct correlation vectors are displayed for family having an absolute Pearson's correlation coefficient (r) greater than 0.6 with NMDS area axis scores. Indirect correlation of environmental variables resulting in an absolute r value cutoff of 0.6 are shown. Vector length is proportional to correlation strength. A stable 3-dimensional solution was found with stress of 15.87.

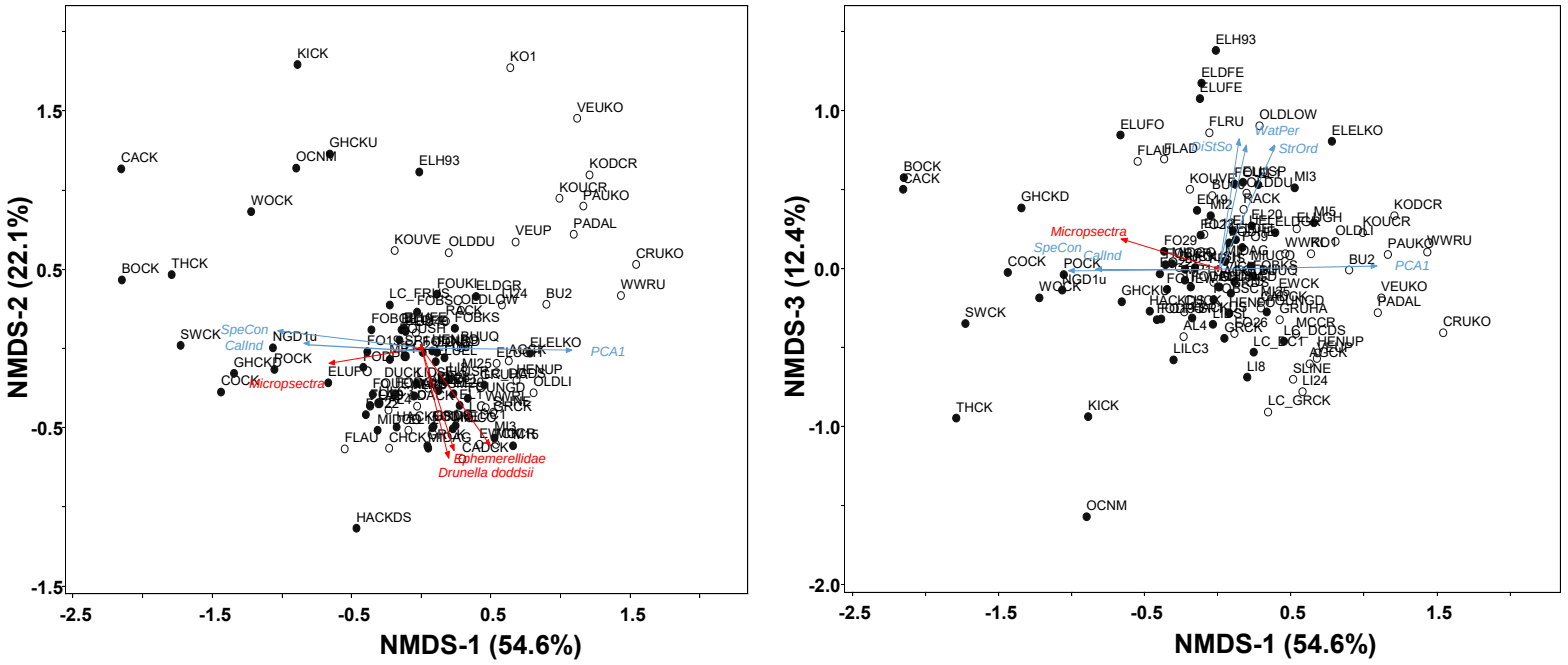

Figure G.10: Nonmetric Multidimensional Scaling Scatter Plot of Benthic Invertebrate Community Structure at 40 Reference Areas (Open Circles) and 59 Mine-exposed Areas (Closed Circles; Log_{10} Transformed Density Matrix, Lowest Practical Level [LPL] of Taxonomy)

Notes: Direct correlation vectors are displayed for LPL having an absolute Pearson's correlation coefficient (r) greater than 0.6 with NMDS area axis scores. Indirect correlation of environmental variables resulting in an absolute r value cutoff of 0.6 are shown. Vector length is proportional to correlation strength. A stable 3-dimensional solution was found with stress of 14.43.

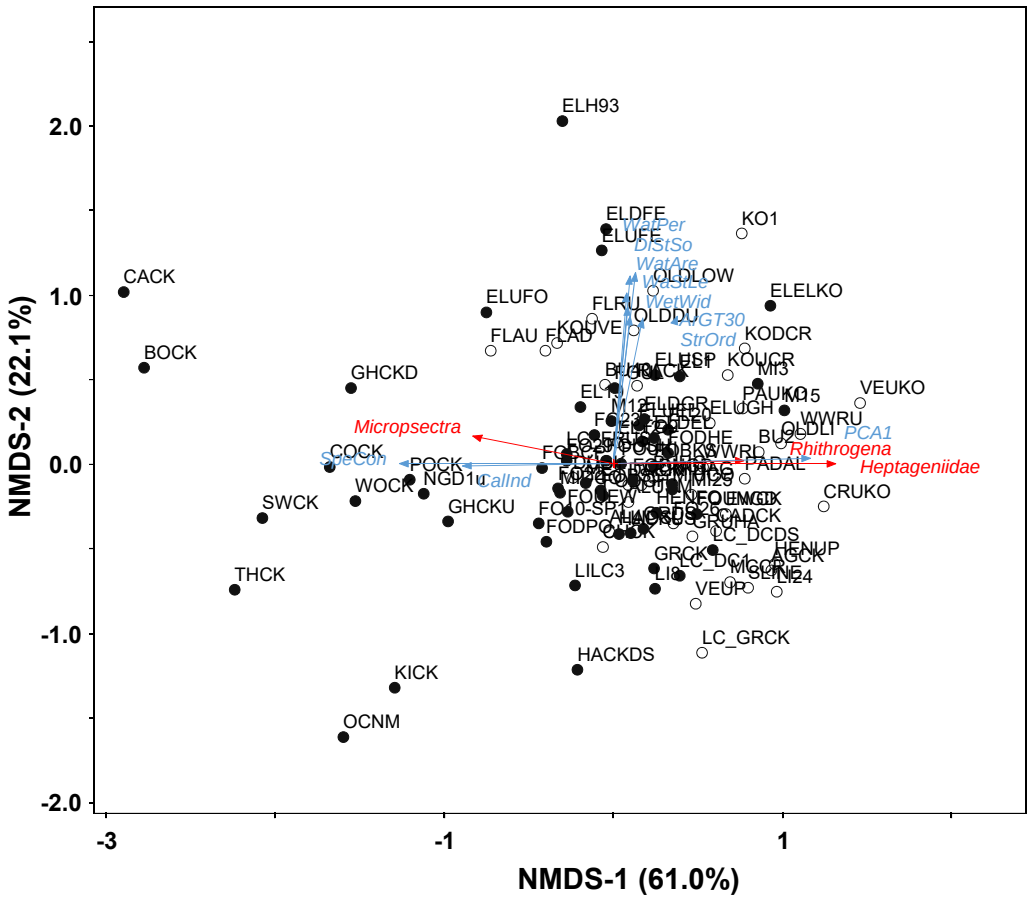

Figure G.11: Nonmetric Multidimensional Scaling Scatter Plot of Benthic Invertebrate Community Structure at 40 Reference Areas (Open Circles) and 59 Mine-exposed Areas (Closed Circles; Fourth Root Transformed Proportional Matrix, Lowest Practical Level [LPL] of Taxonomy)

Notes: Direct correlation vectors are displayed for LPL having an absolute Pearson's correlation coefficient (r) greater than 0.6 with NMDS area axis scores. Indirect correlation of environmental variables resulting in an absolute r value cutoff of 0.6 are shown. Vector length is proportional to correlation strength. A stable 2-dimensional solution was found with stress of 20.34.

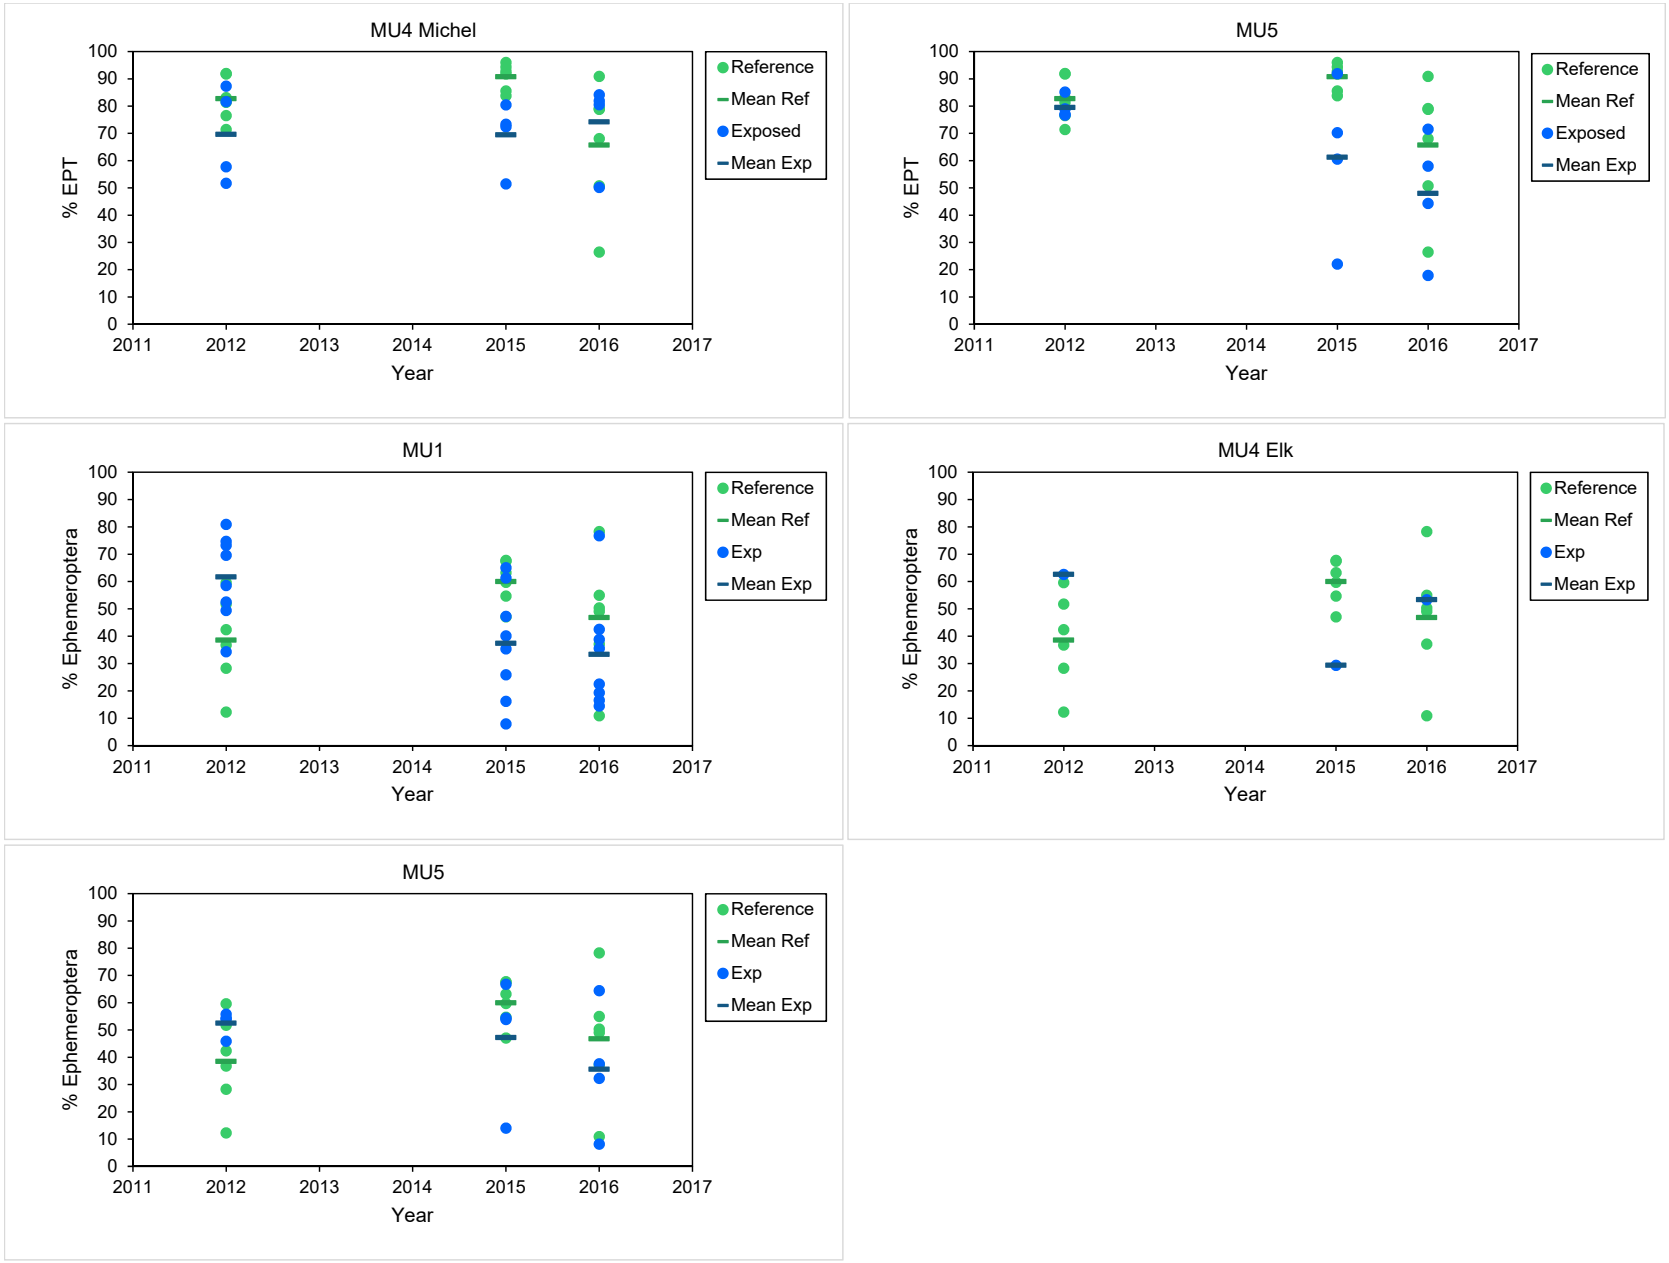

Figure G.12: Scatterplots of Benthic Invertebrate Endpoints for the Mean Reference and Mean Main Stem Mine-exposed Areas by Management Unit for Comparisons that had at Least One Significant Contrast Relative to Reference

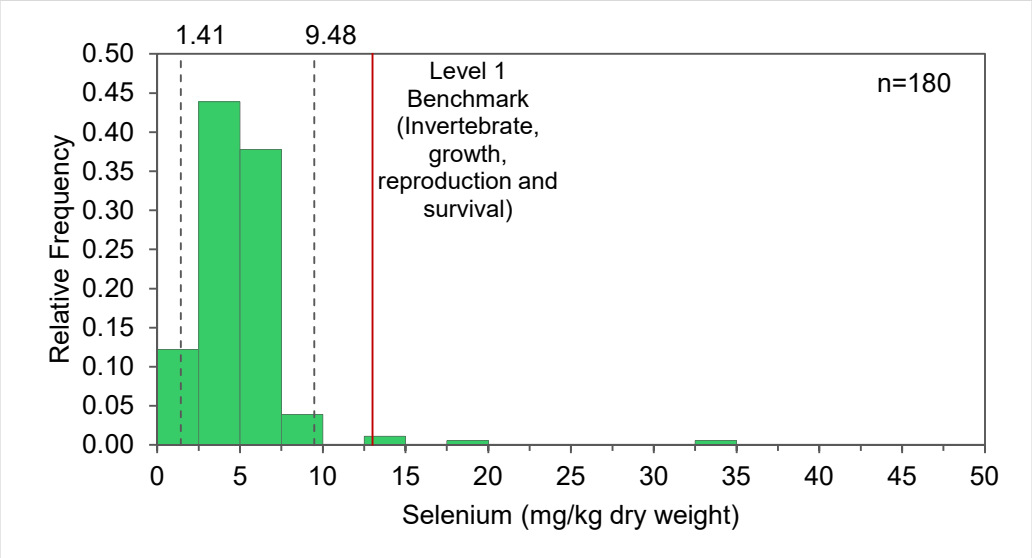

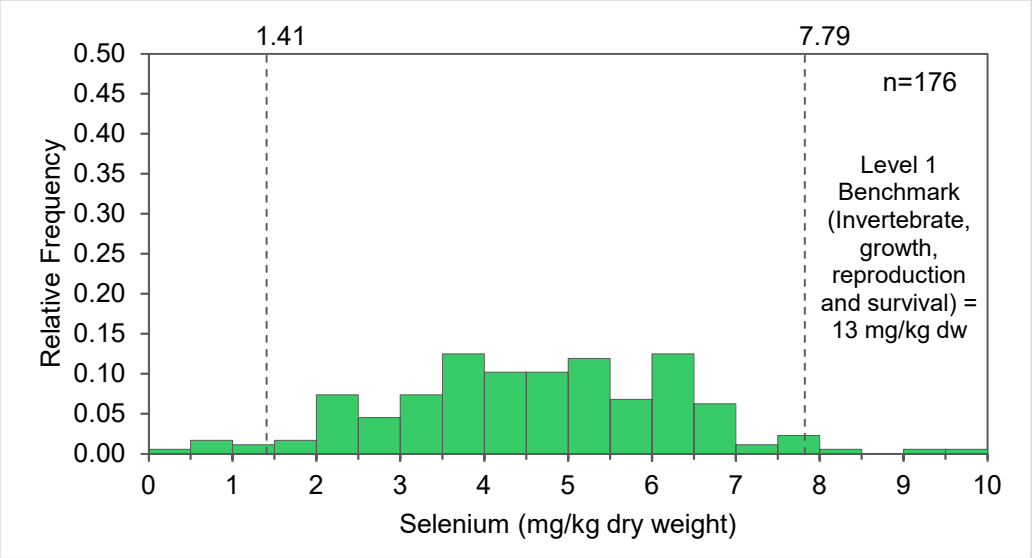

Figure G.13: Distribution of Reference Area Data (n = 180) for all Areas (top) and After Outlier Removal (n = 176; bottom) for Tissue Selenium Concentrations for Composite Benthic Invertebrates Samples in the Elk Valley, 1996 - 2015

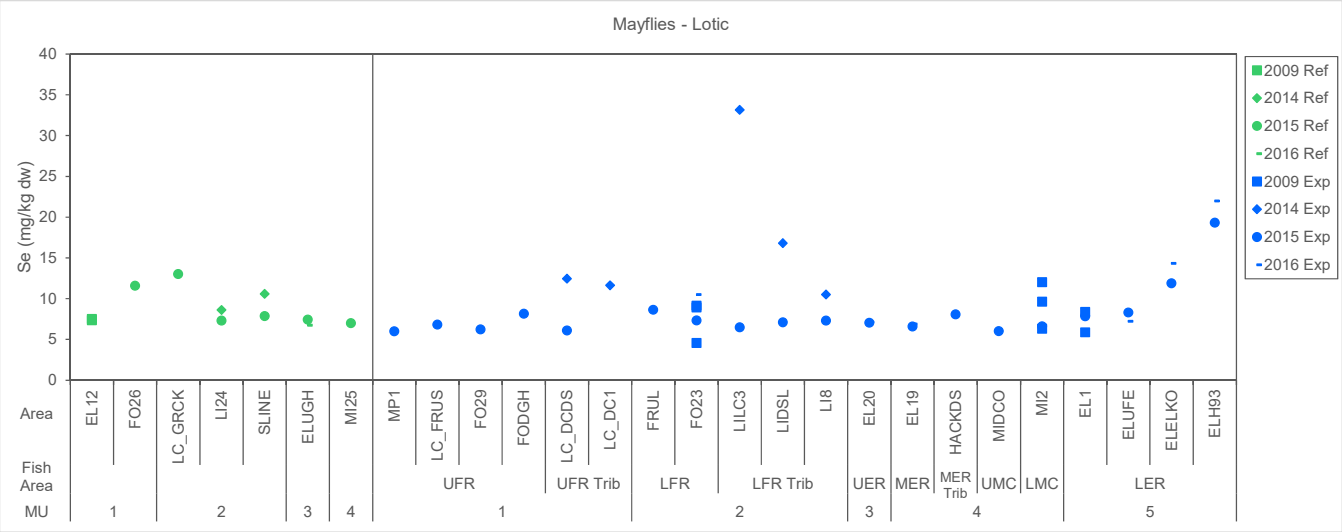
Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles. 4 outliers were identified.



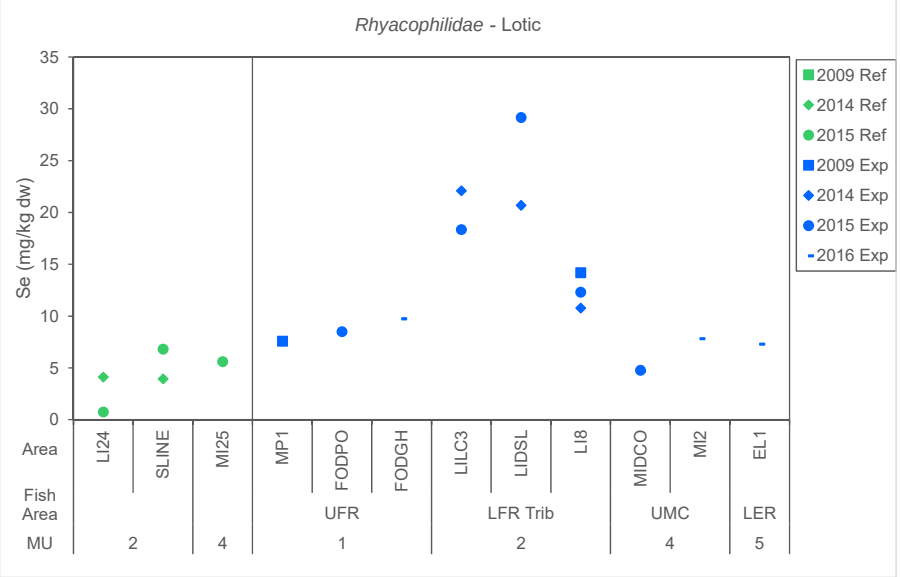


Figure G.14: Selenium Concentrations in Single-Taxon Benthic Invertebrate Samples Collected in Lotic and Lentic Habitats, 2006 - 2015

Notes: UFR = Upper Fording River; LFR = Lower Fording River; UER = Upper Elk River; MER = Middle Elk River; UMC = Upper Michel Creek; LMC = Lower Michel Creek; LER = Lower Elk River; Trib = Tributaries

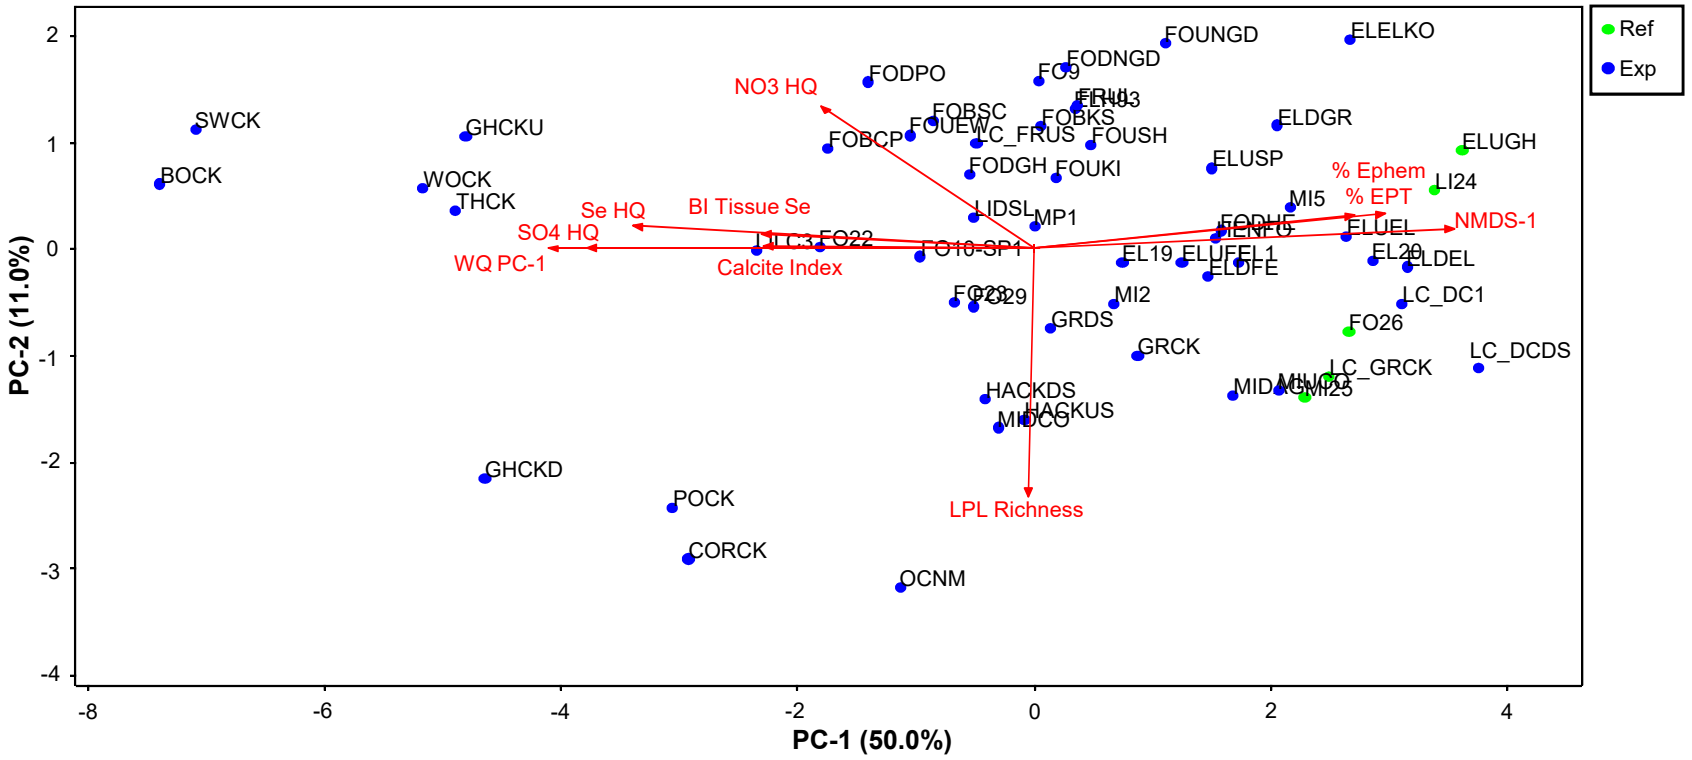

Figure G.15: Overall Principal Components Analysis Biplot of Biological and Abiotic Summary Variables Based on Data from 5 Reference and 53 Mine-exposed Areas, September 2015, Elk Valley

Note: Direct correlation vectors are displayed for variables having an absolute Pearson's correlation coefficient (r) greater than 0.6 with PCA axis scores. Vector length is proportional to correlation strength. Note that PC-2 is not a significant axis (Monte carlo simulation $p > 0.05$).

r ≥ 0.6 or r ≤ -0.6

P-value < 0.05

Note: PCA Details in Appendix A.

[a] HQ - hazard quotient. Observed concentration divided by Level 1 effect benchmark defined in the Elk Valley Water Quality Plan (selenium, sulphate, nitrate, cadmium), the upper normal range limit defined by Minnow (2016b; calcite index), or BC water quality guidelines (the other water quality variables), as applicable.

[b] Selenium, sulphate, nitrate.

Table G.7: Correlation of Benthic Invertebrate Community Endpoints for Reference (n = 40) and Mine-exposed (n = 59) Areas Sampled in September 2015

value > upper limit ($P_{97.5}$) of the normal range

value < lower limit ($P_{2.5}$) of the normal range

[a] Axis is scaled so that it is positively correlated with PC-1 for water quality (i.e. multiplied by -1 when negatively correlated with PC-1)

[b] Percentiles based on 2015 reference area disitrbution (n = 40) prior to outlier evaluation

Table G.8: Comparison of Benthic Invertebrate Community Endpoints for Reference (n = 40) and Mine-exposed Areas (n = 59) in the Elk Valley to the 2.5th and 97.5th Percentiles (Prior to the Outlier Evaluation) for the 2015 Reference Area Distribution, September 2015

Exposure Type	Management Unit	Main Watershed	Stream Type (M-main stem; T-tributary)	Biological Area Code	Univariate Indicators									Univariate Indicators (significantly correlated with WQ PC-1)					Axis 1 Scores from NMDS Ordinations[a] (significantly correlated with WQ PC-1)

Note: Results were before and after the removal of potential outliers. Coloured cells show individual reference area values that were at the low (blue shade) and high (gold shade) ends of the distribution range. Green highlights the reference area data set recommended for the evaluation of communities in mine-exposed areas.

- data set was used to define the normal range (2.5th and 97.5th percentiles)
- outlier or value removed from estimation of percentiles
- value < 2.5th percentile of reference distribution
- value < 5th percentile of reference distribution
- value < 10th percentile of reference distribution
- value < 25th percentile of reference distribution
- value > 75th percentile of reference distribution
- value > 90th percentile of reference distribution
- value > 95th percentile of reference distribution
- value > 97.5th percentile of reference distribution

[a] 3-D Ordination (relative abundance/fourth root transformed). The NMDS Axis is scaled so that it is positively correlated with PC-1 for water quality (i.e. multiplied by -1 when negatively correlated with PC-1)

Table G.11: Spearman Correlation of Environmental Variables with Endpoints for Reference (n = 40) Areas Sampled in September 2015

Variables		Total Abundance	LPL Richness	EPT LPL Richness	% EPT	% Ephemeroptera	NMDS Axis 1[a]

Notes: Normal range estimates are the 2.5th and 97.5th percentiles of the 2012 and 2015 reference area data distribution (benthic invertebrates) and 2015 reference area data distribution (periphyton) after the removal of outliers

value > upper limit ($P_{97.5}$) of the normal range

value < lower limit ($P_{2.5}$) of the normal range

Table G.13: Comparison of Key Benthic Invertebrate and Periphyton Community Endpoints for Reference (n = 40) and Mine-exposed Areas (n = 59) Sampled September, 2015 in the Elk Valley to the Normal Ranges

[a] mean of triplicate samples

[b] Value is suspect due to low sample volume. Not included in analyses.

Value > Level 1 benchmark of 11 mg/kg dw for dietary effects to fish (Level 1 benchmark for effects to invertebrates is 13.0 mg/kg dw)

Value > upper limit of normal range of (7.79 mg/kg dw)

Notes: "-" = not sampled

* Data are suspect due to low sample volume.

[a] Hazard quotient was calculated as tissue selenium concentration divided by the Level 1 Benchmark (Golder, 2014c): 13 mg/kg for growth, reproduction, and survival of benthic invertebrates; 11 mg/kg for dietary effects to juvenile fish; and 15 mg/kg for dietary effects to birds.

Maximum concentration reported from replicate samples

Good (Quotient < 0.7)

Marginal (Quotient between 0.7 and 1.0)

Poor (Quotient > 1.0)

FISH

Longnose Sucker
Westslope Cutthroat Trout
Mountain Whitefish

FISH

Longnose Sucker

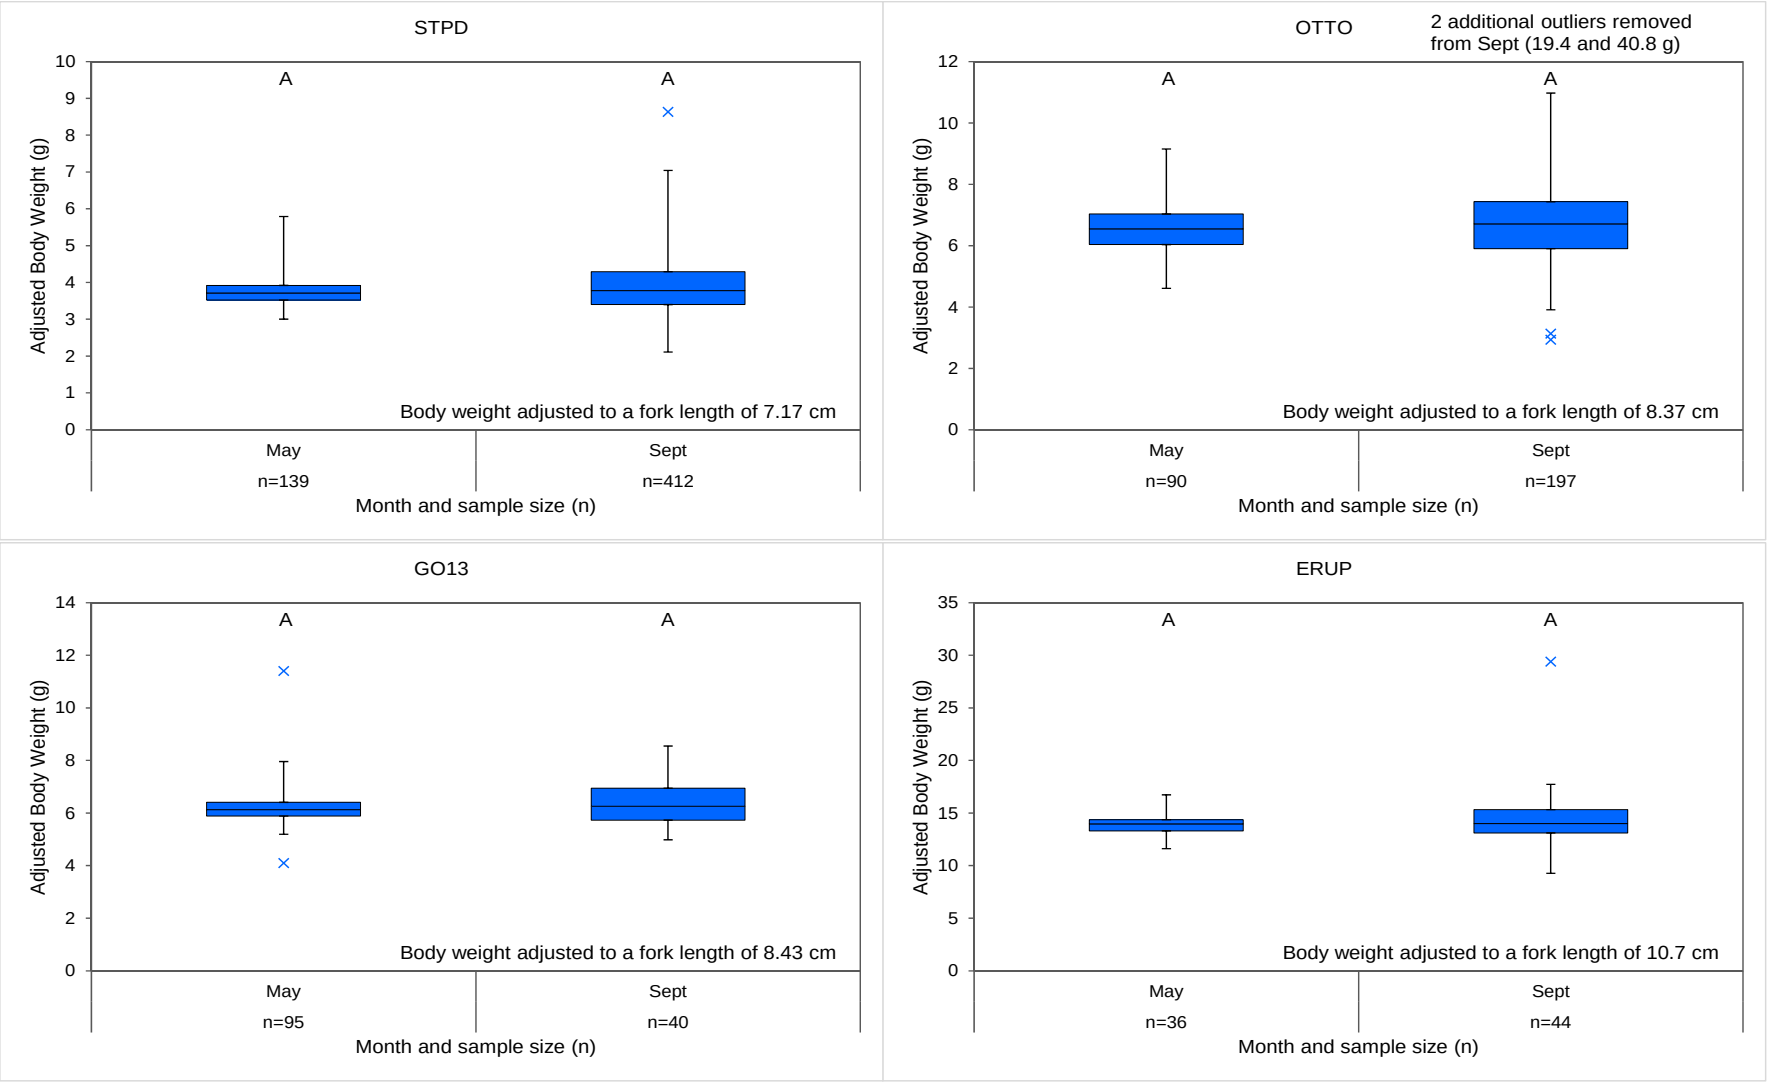

Figure HLSU.1: Boxplots of Condition (Body Weight Adjusted to the Mean Fork Length) from the Analysis of Covariance Model for Longnose Sucker Collected in May 2015 Compared to September 2015 by Area

Notes: Whiskers of the boxplots extend to the minimum and maximum values included in the statistical analyses. The outliers removed from statistical analyses are noted by an ×
Time periods that share a letter (A) are not significantly different (p-value > 0.05). Time periods that do not share a letter are significantly (p-value < 0.05) different. Results of statistical analyses are in Table HLSU.11.

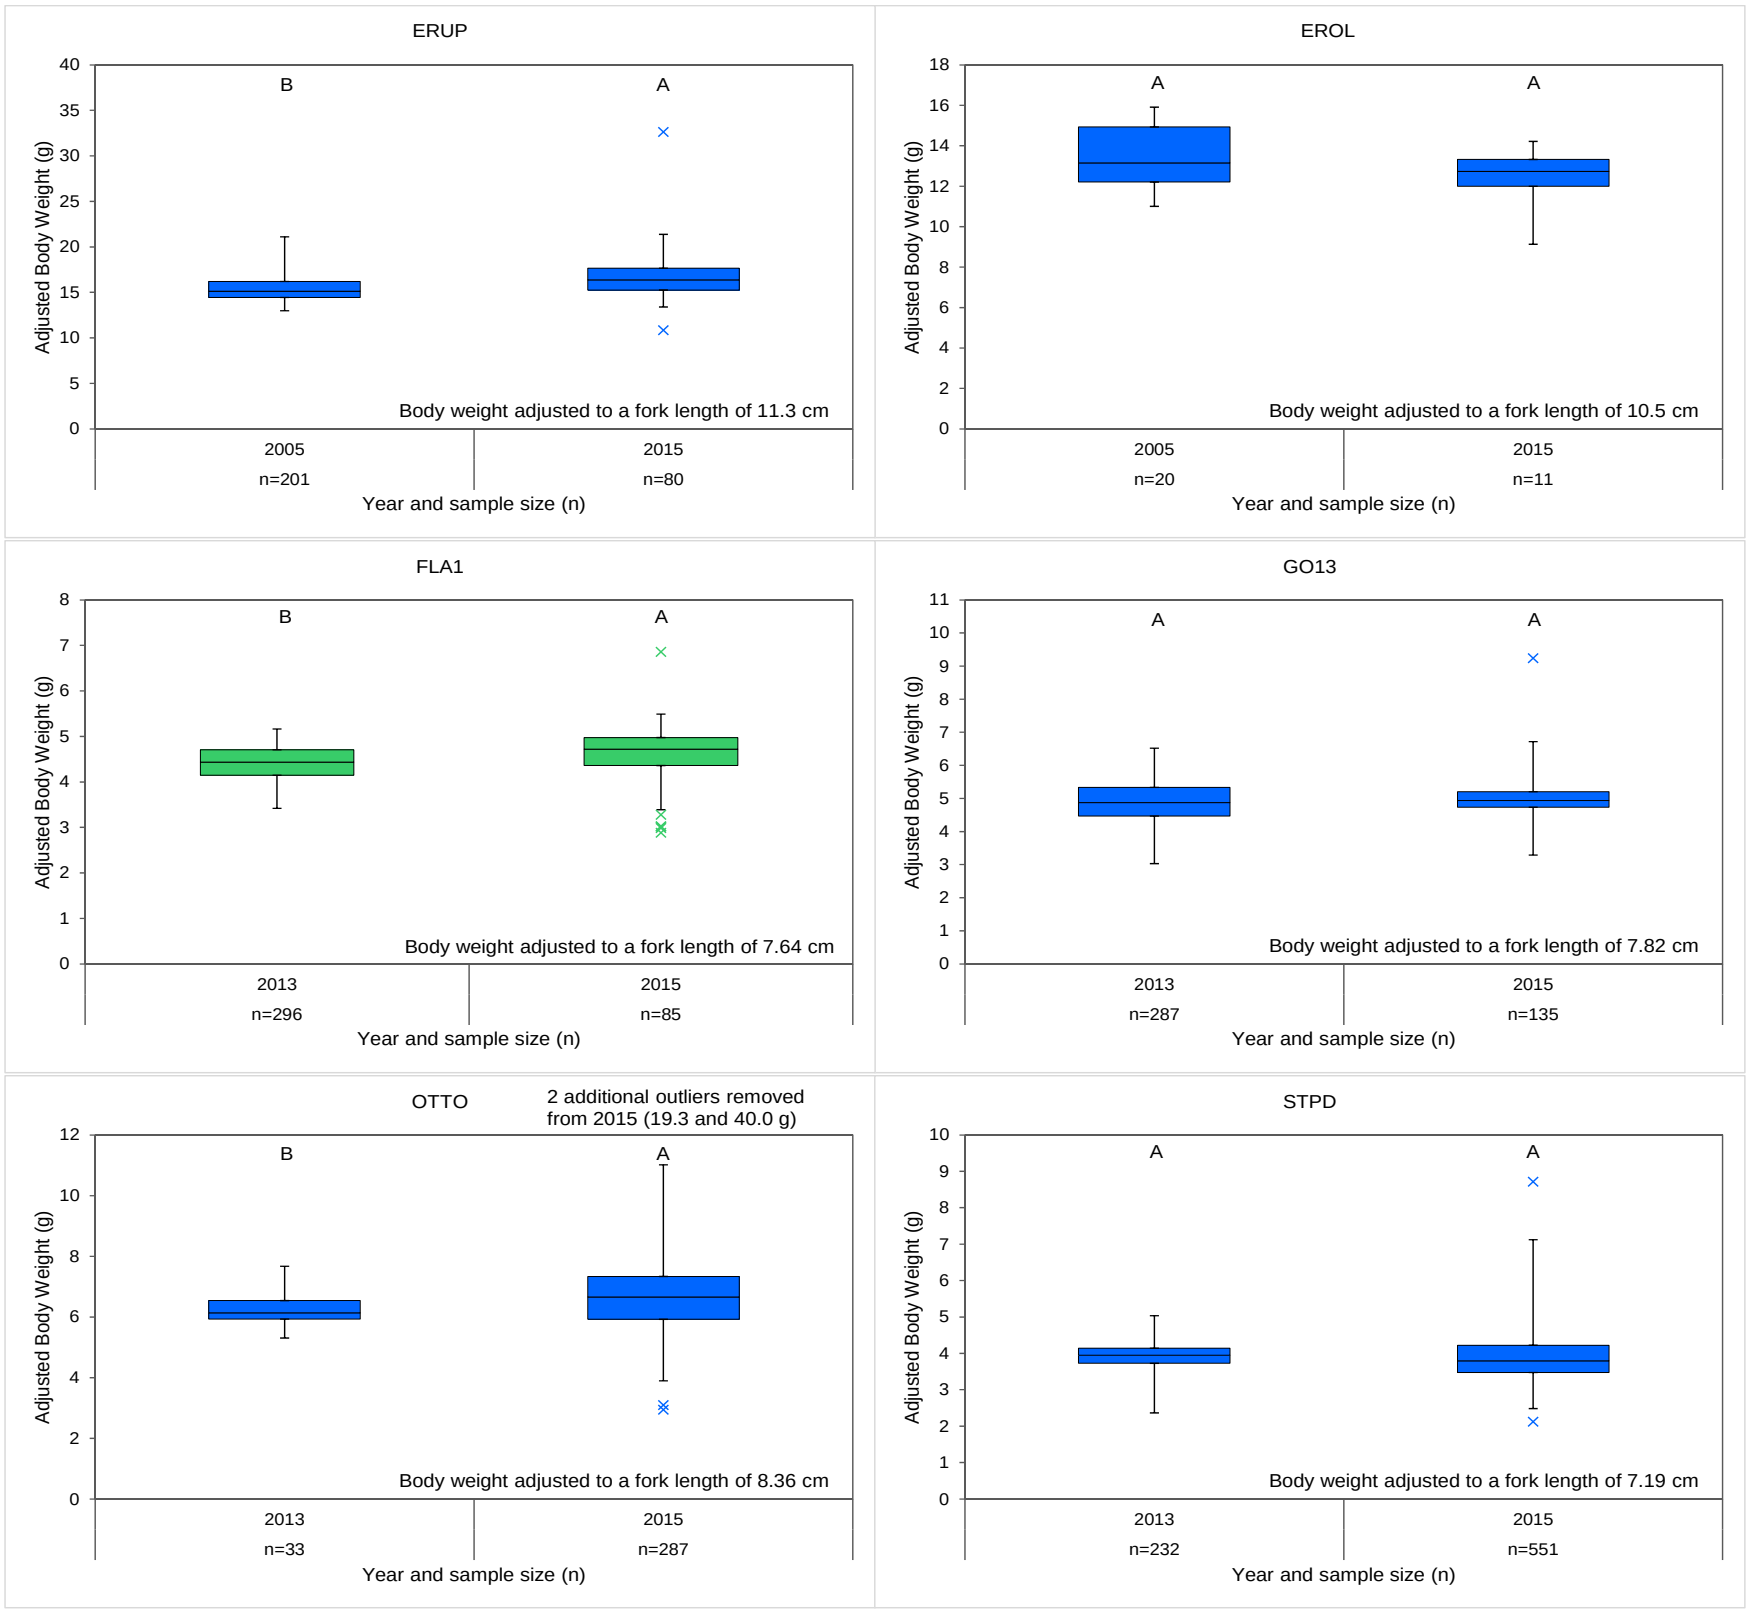

Figure HLSU.2: Boxplots of Body Weight Adjusted to the Mean Fork Length from the Analysis of Covariance Model for Longnose Sucker Collected in 2005 or 2013 Compared to 2015 by Area

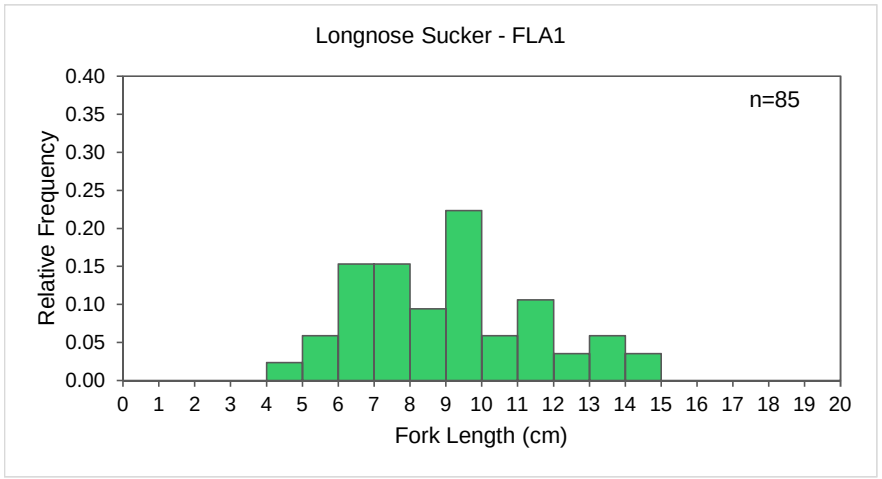
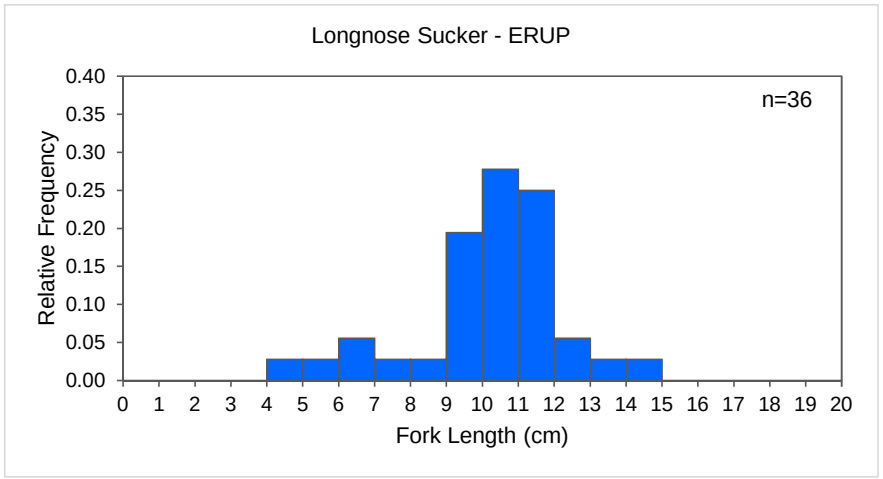
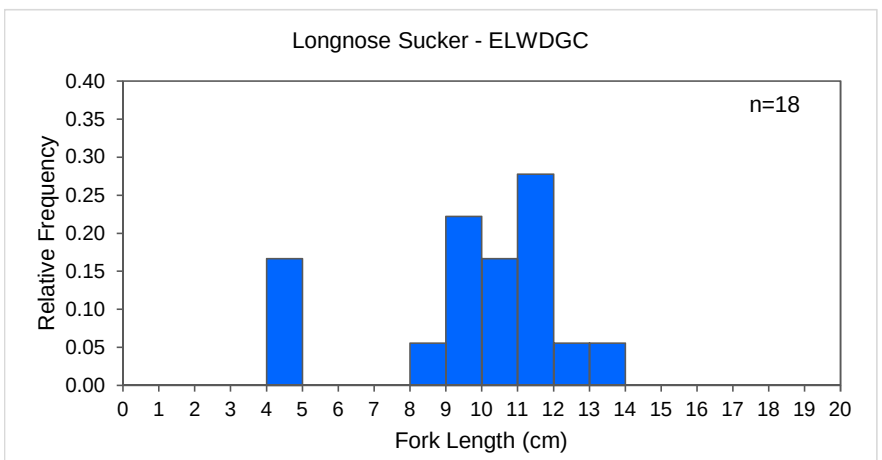
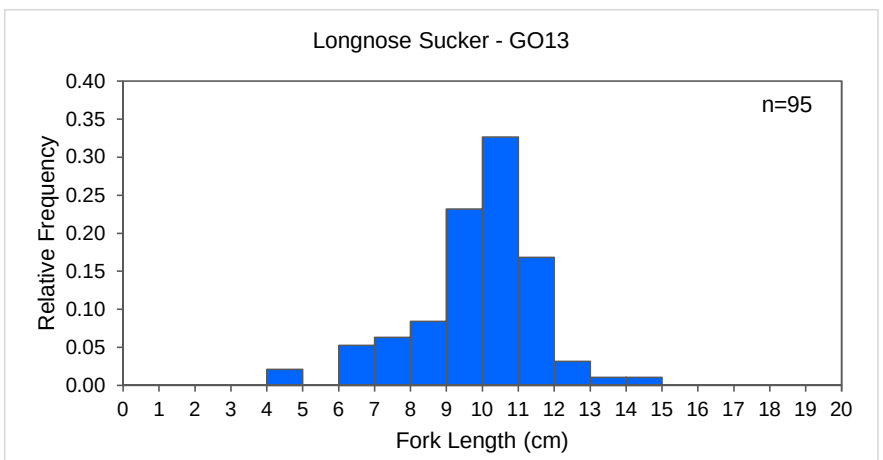
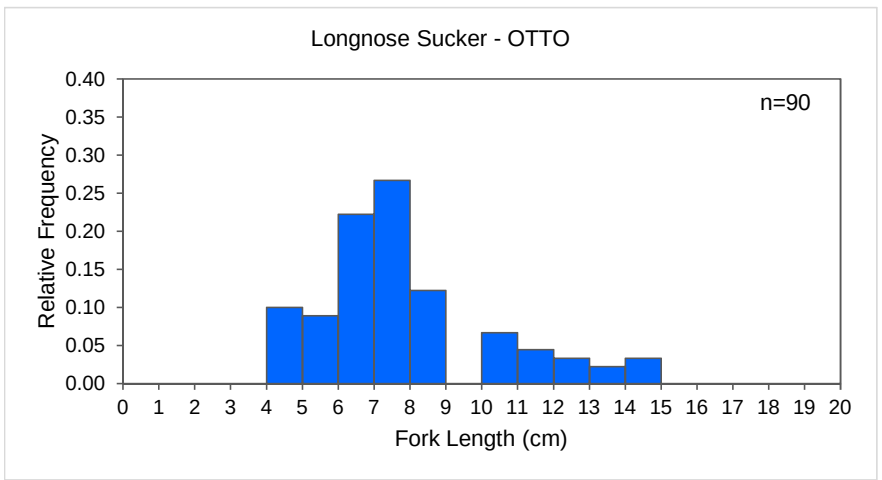
Notes: Whiskers of the boxplots extend to the minimum and maximum values included in the statistical analyses. The outliers removed from statistical analyses are noted by an ×
Years that share a letter (A) are not significantly different (p-value > 0.05). Years that do not share a letter are significantly (p-value < 0.05) different. Results of statistical analyses are in Table HLSU.12.

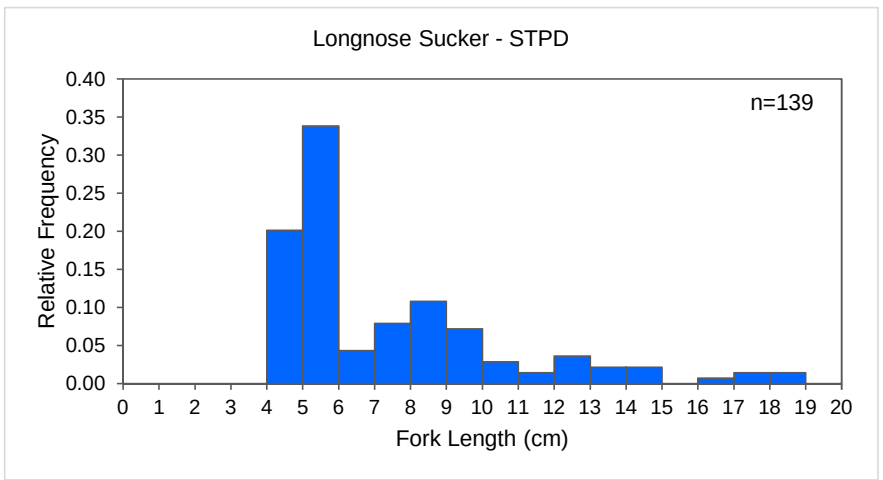


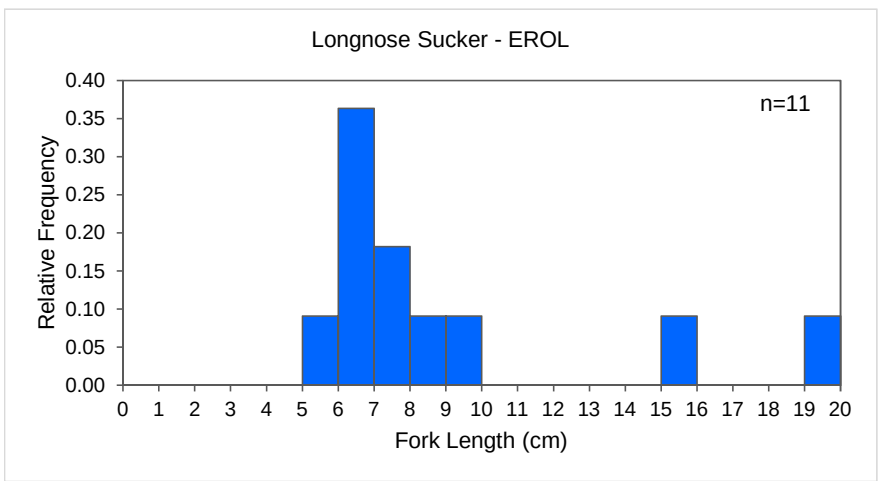












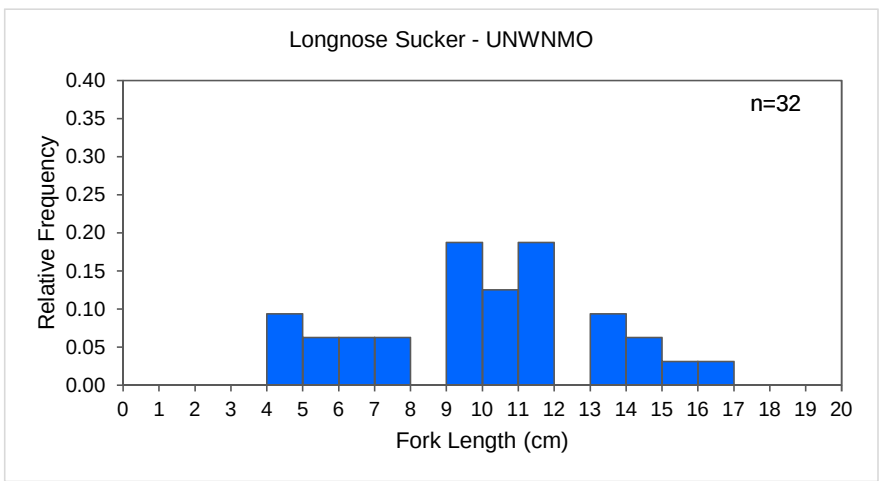


Figure HLSU.3: Length Frequency Distributions for Longnose Sucker Among Reference (Green) and Mine-exposed (Blue) Areas, May 2015

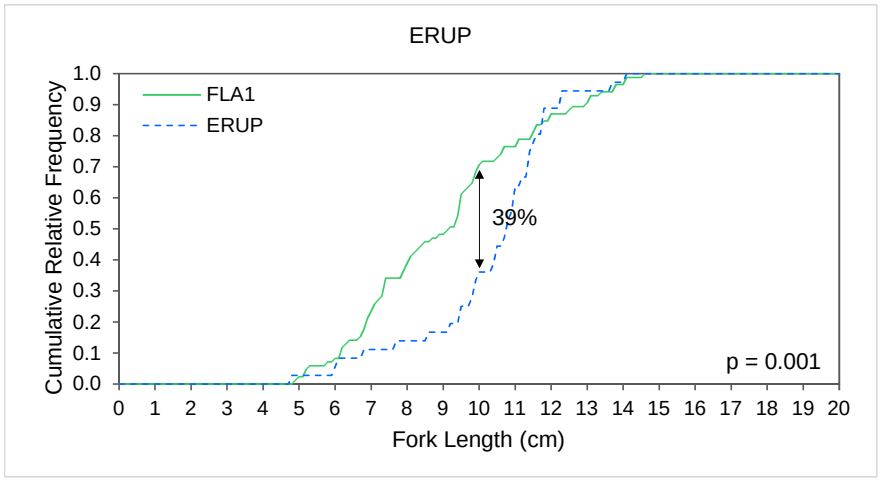

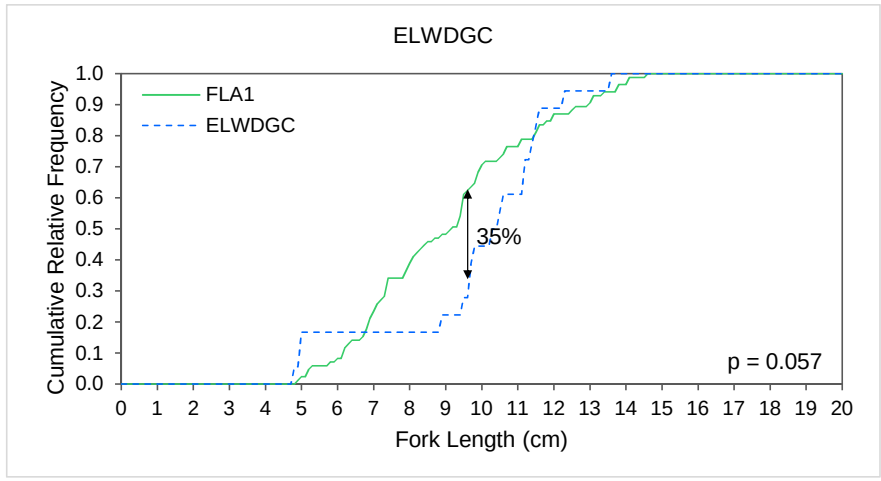

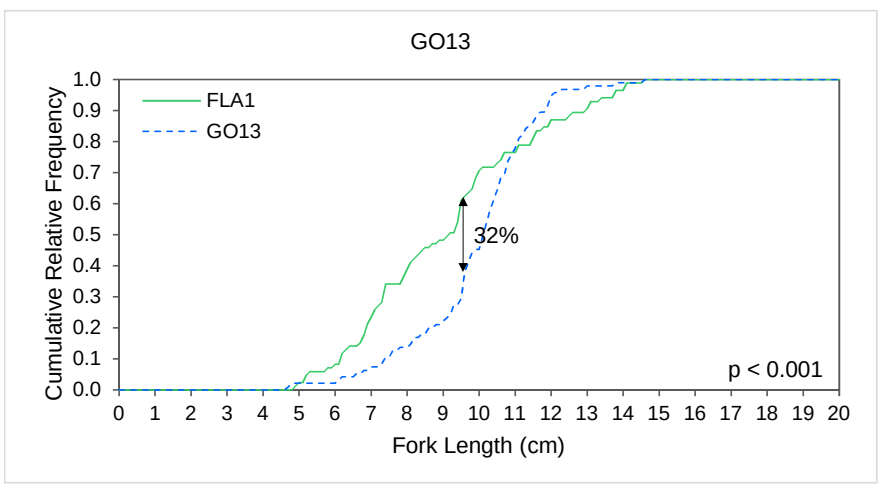

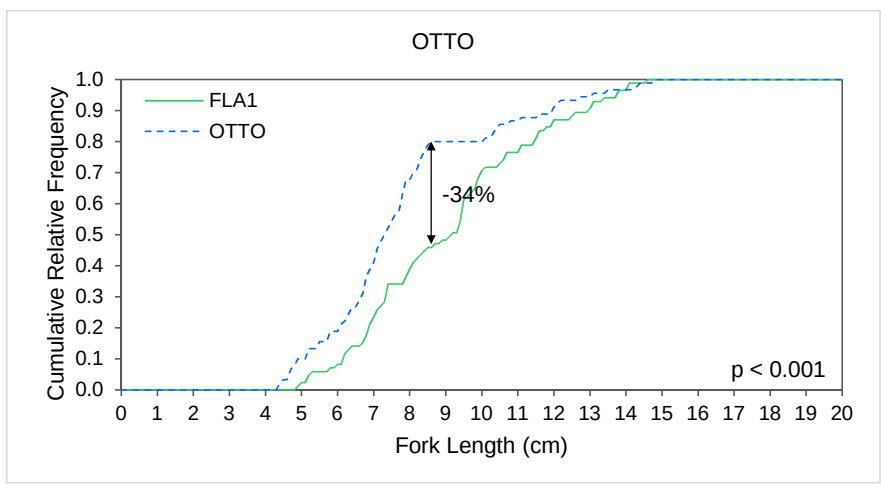

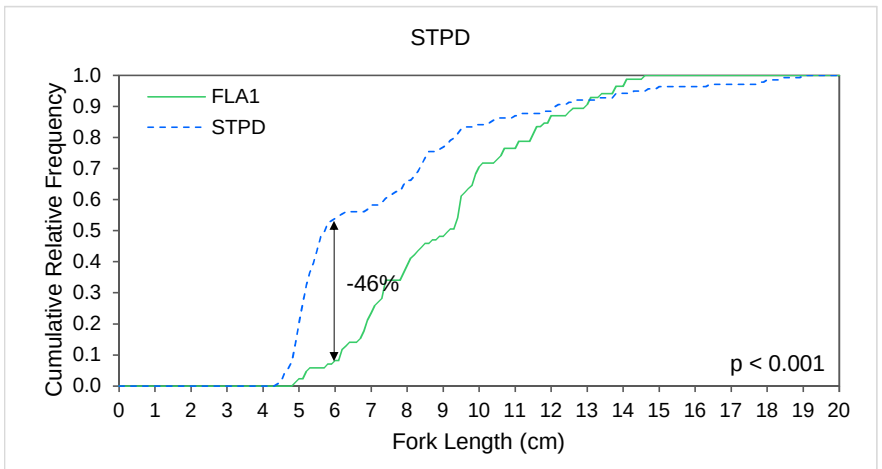

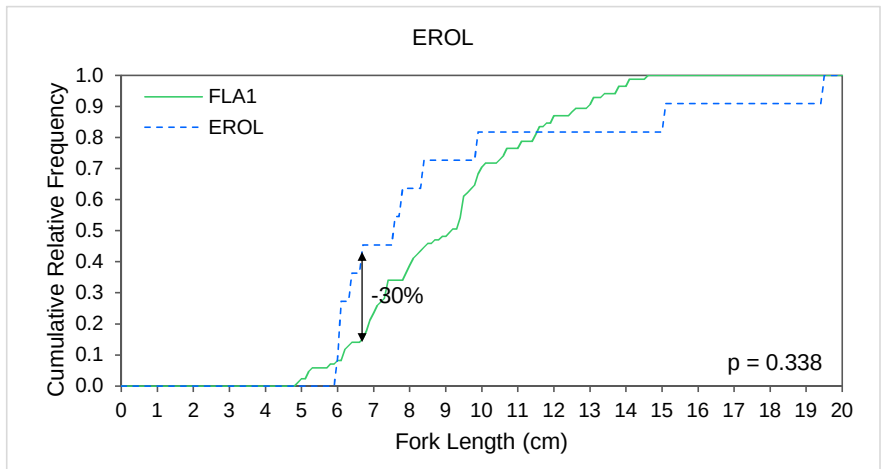

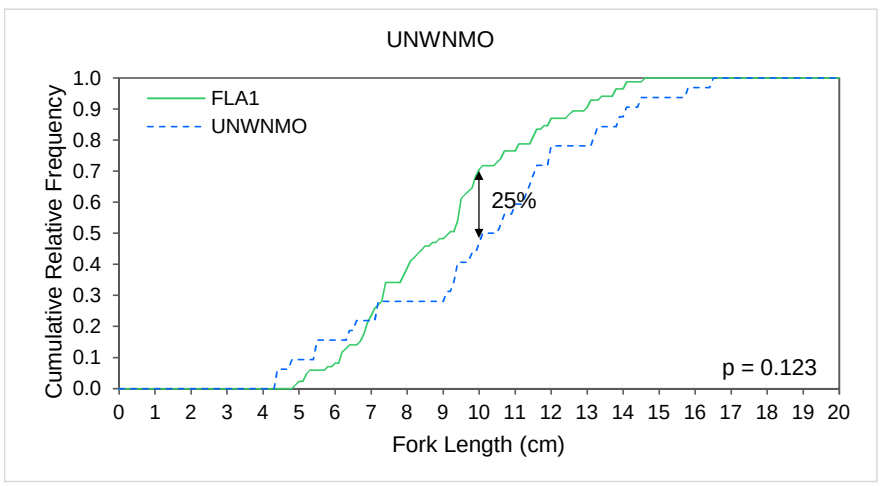

Figure HLSU.4: Cumulative Relative Frequency Distributions for Fork Length of Longnose Sucker for Areas Compared with the Two-sample Kolmogorov-Smirnov Test Between FLA-1 (Reference; Green) and Mine-exposed Areas (Blue), May 2015

Notes: Magnitude of difference = the maximum difference between the cumulative relative frequency distributions. P-value reported for the two-sample Kolmogorov-Smirnov test

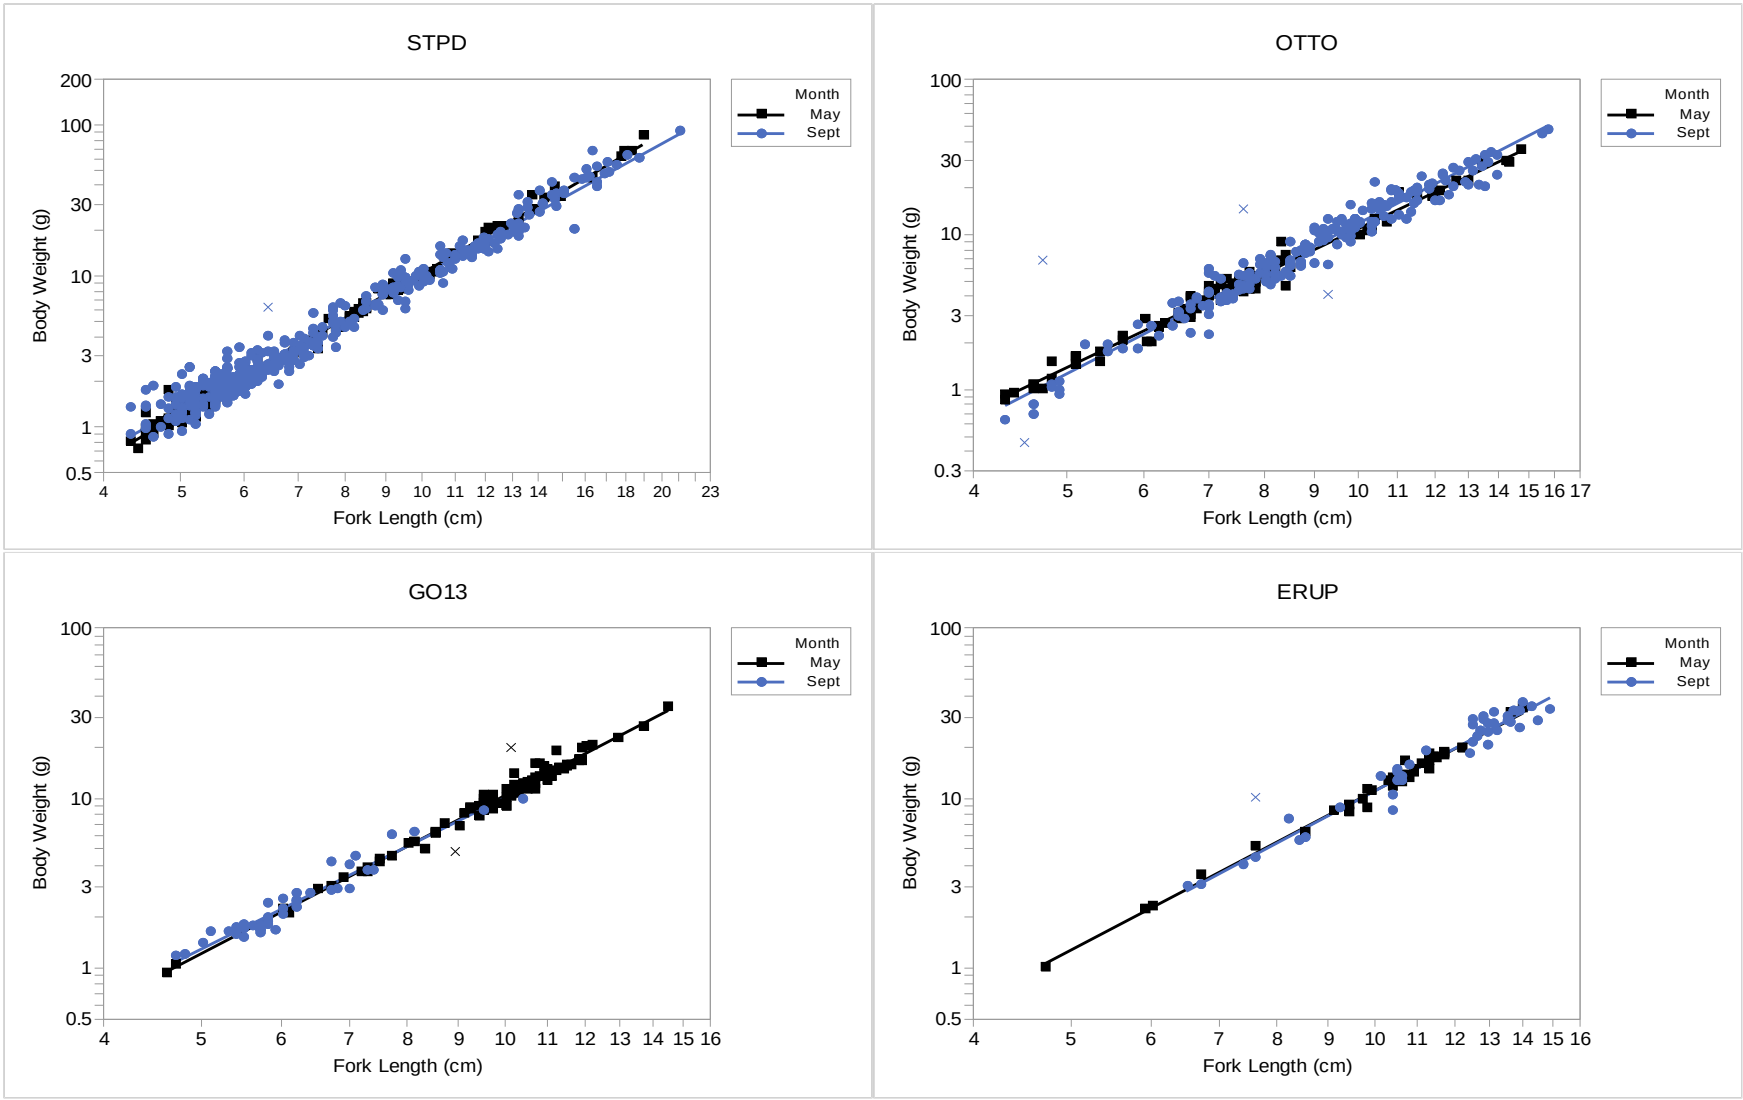

Figure HLSU.5: Scatterplots and Linear Regressions of Body Weight versus Fork Length for Longnose Sucker Collected in May and September, 2015 by Area

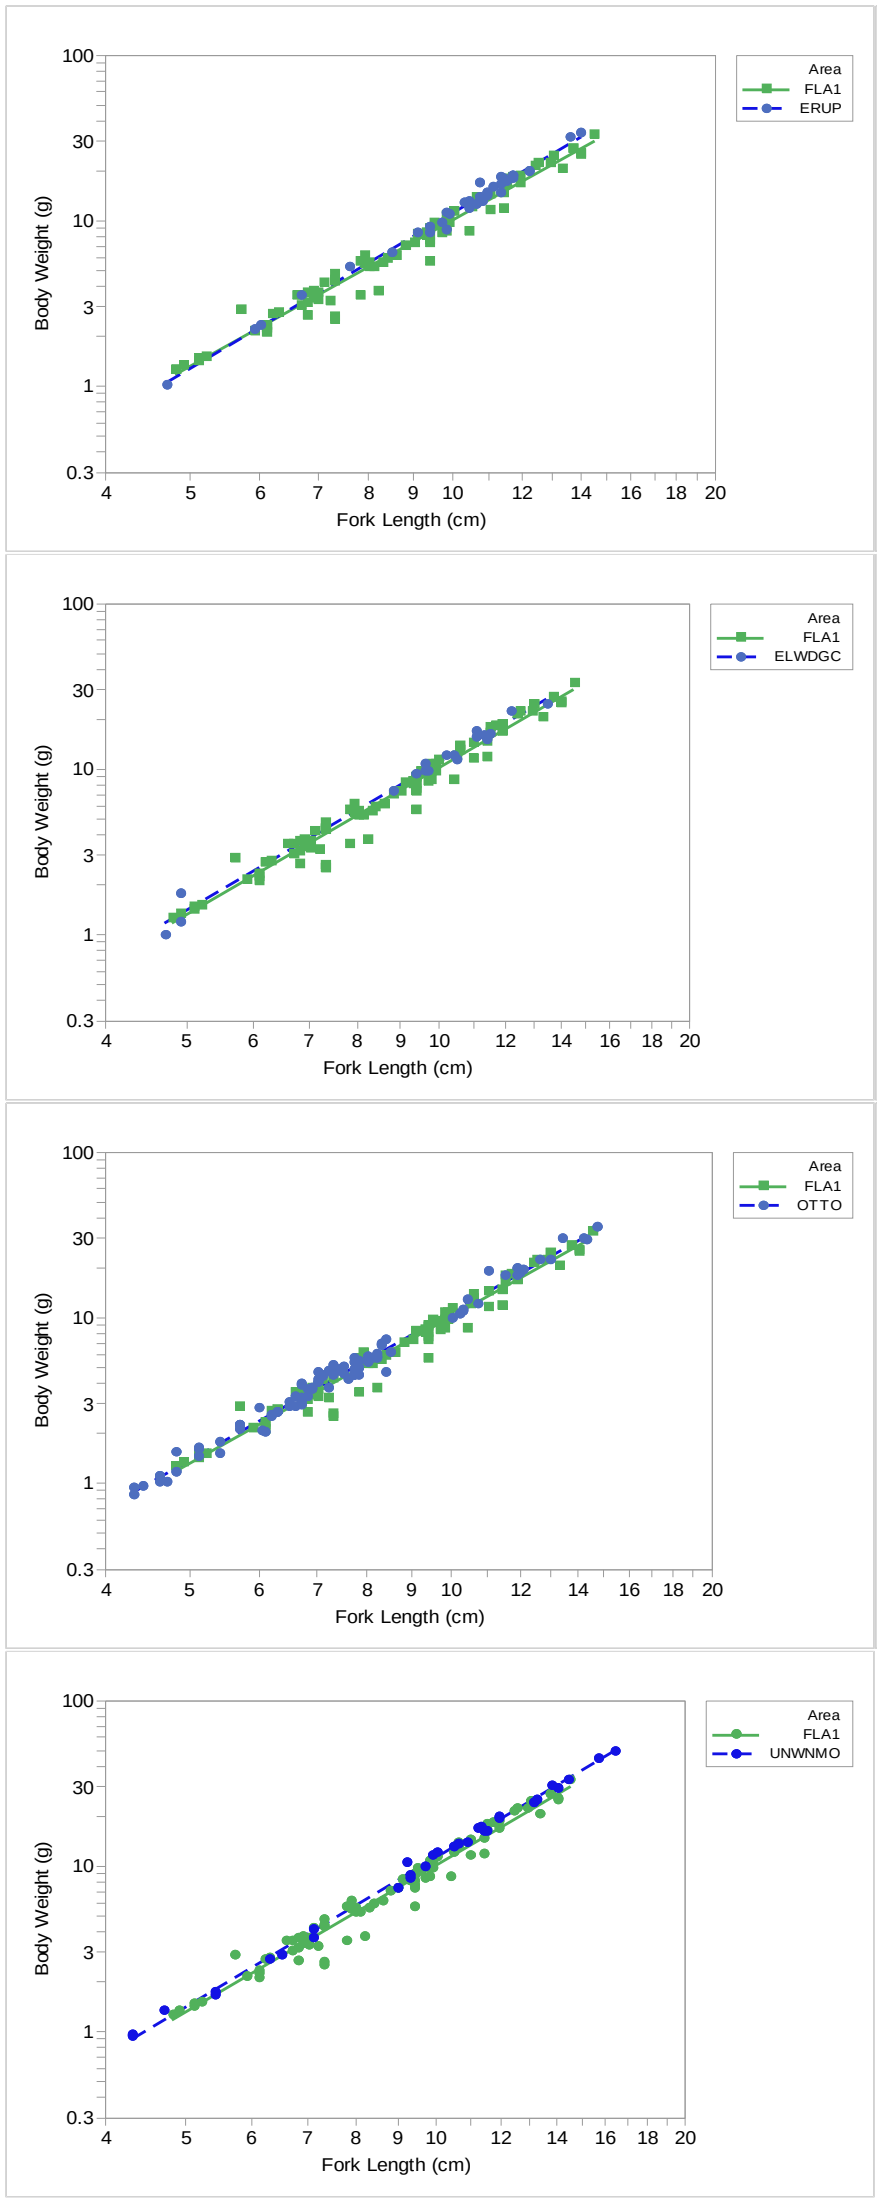
Notes: Outliers removed from statistical analyses are noted by an ×



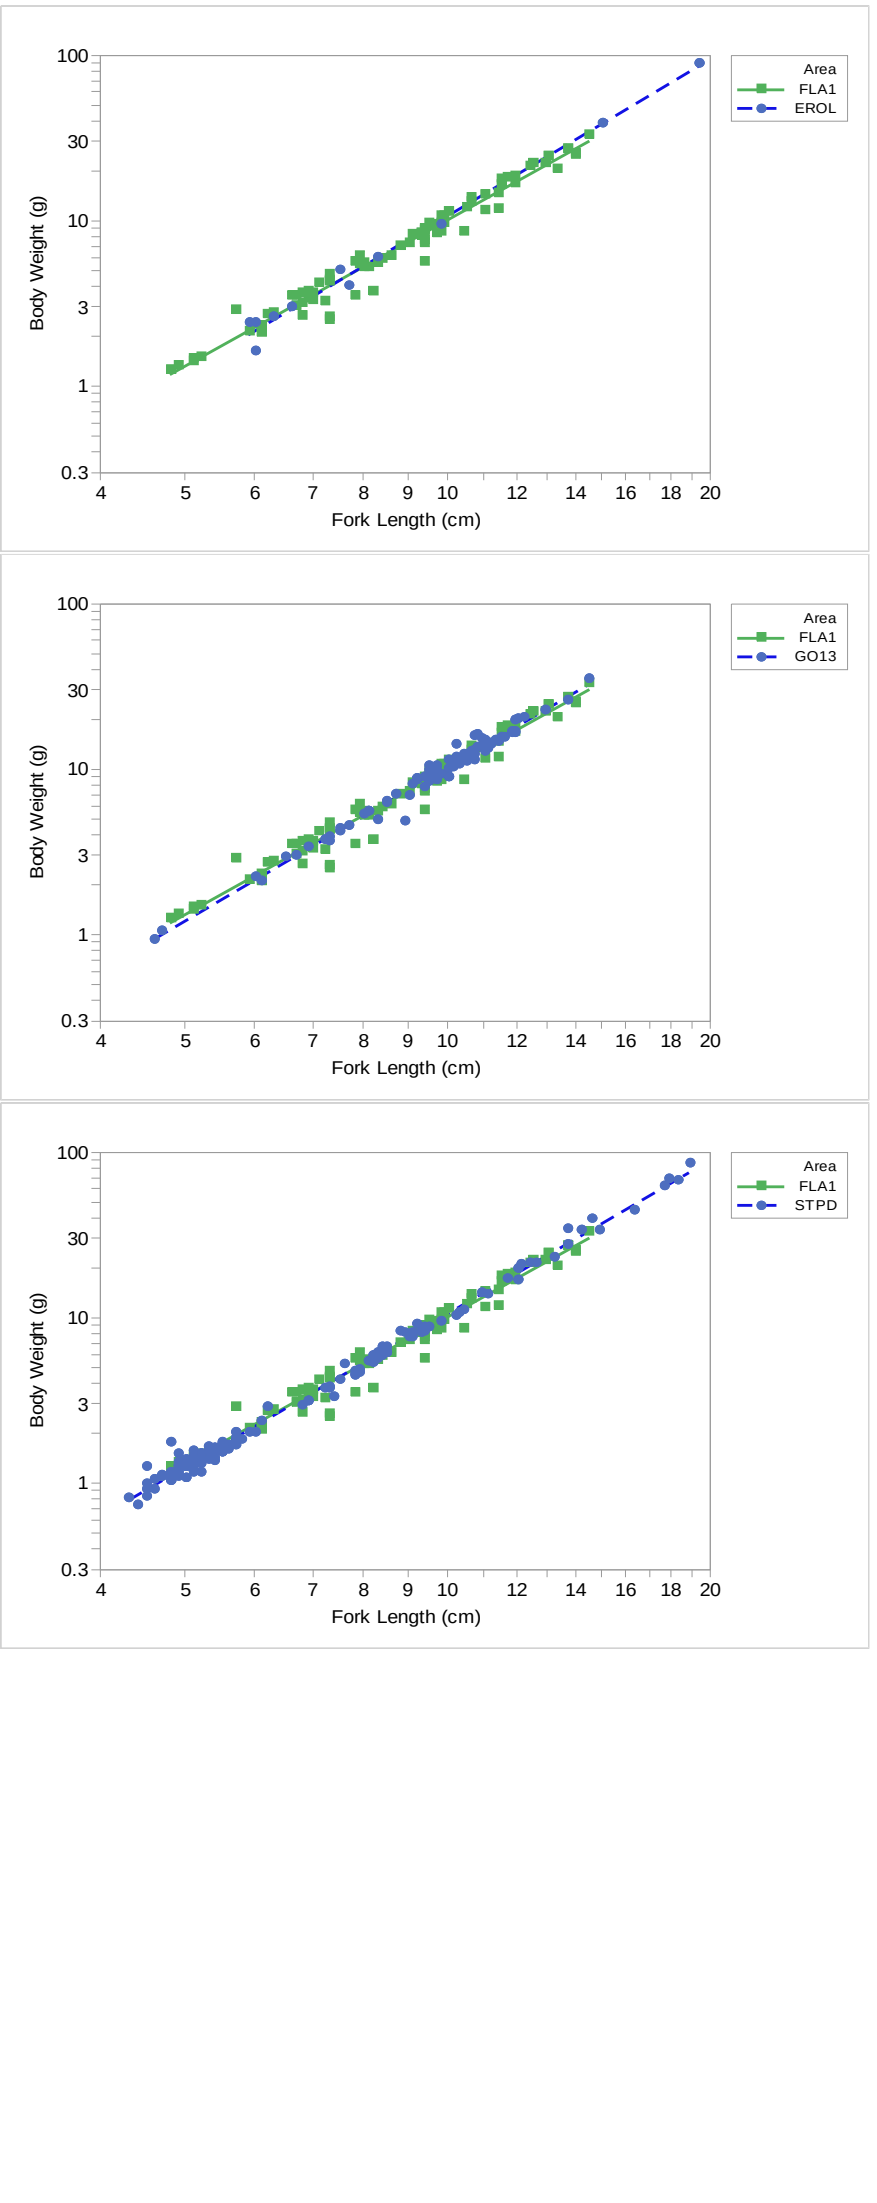


Figure HLSU.6: Scatterplots and Linear Regressions of Body Weight versus Fork Length from Each Mine-exposed Area (ERUP, EROL, ELWDGC, GO13, OTTO, STPD, UNWNMO) Relative to the the Reference Area (FLA1) for Longnose Sucker Collected in May, 2015

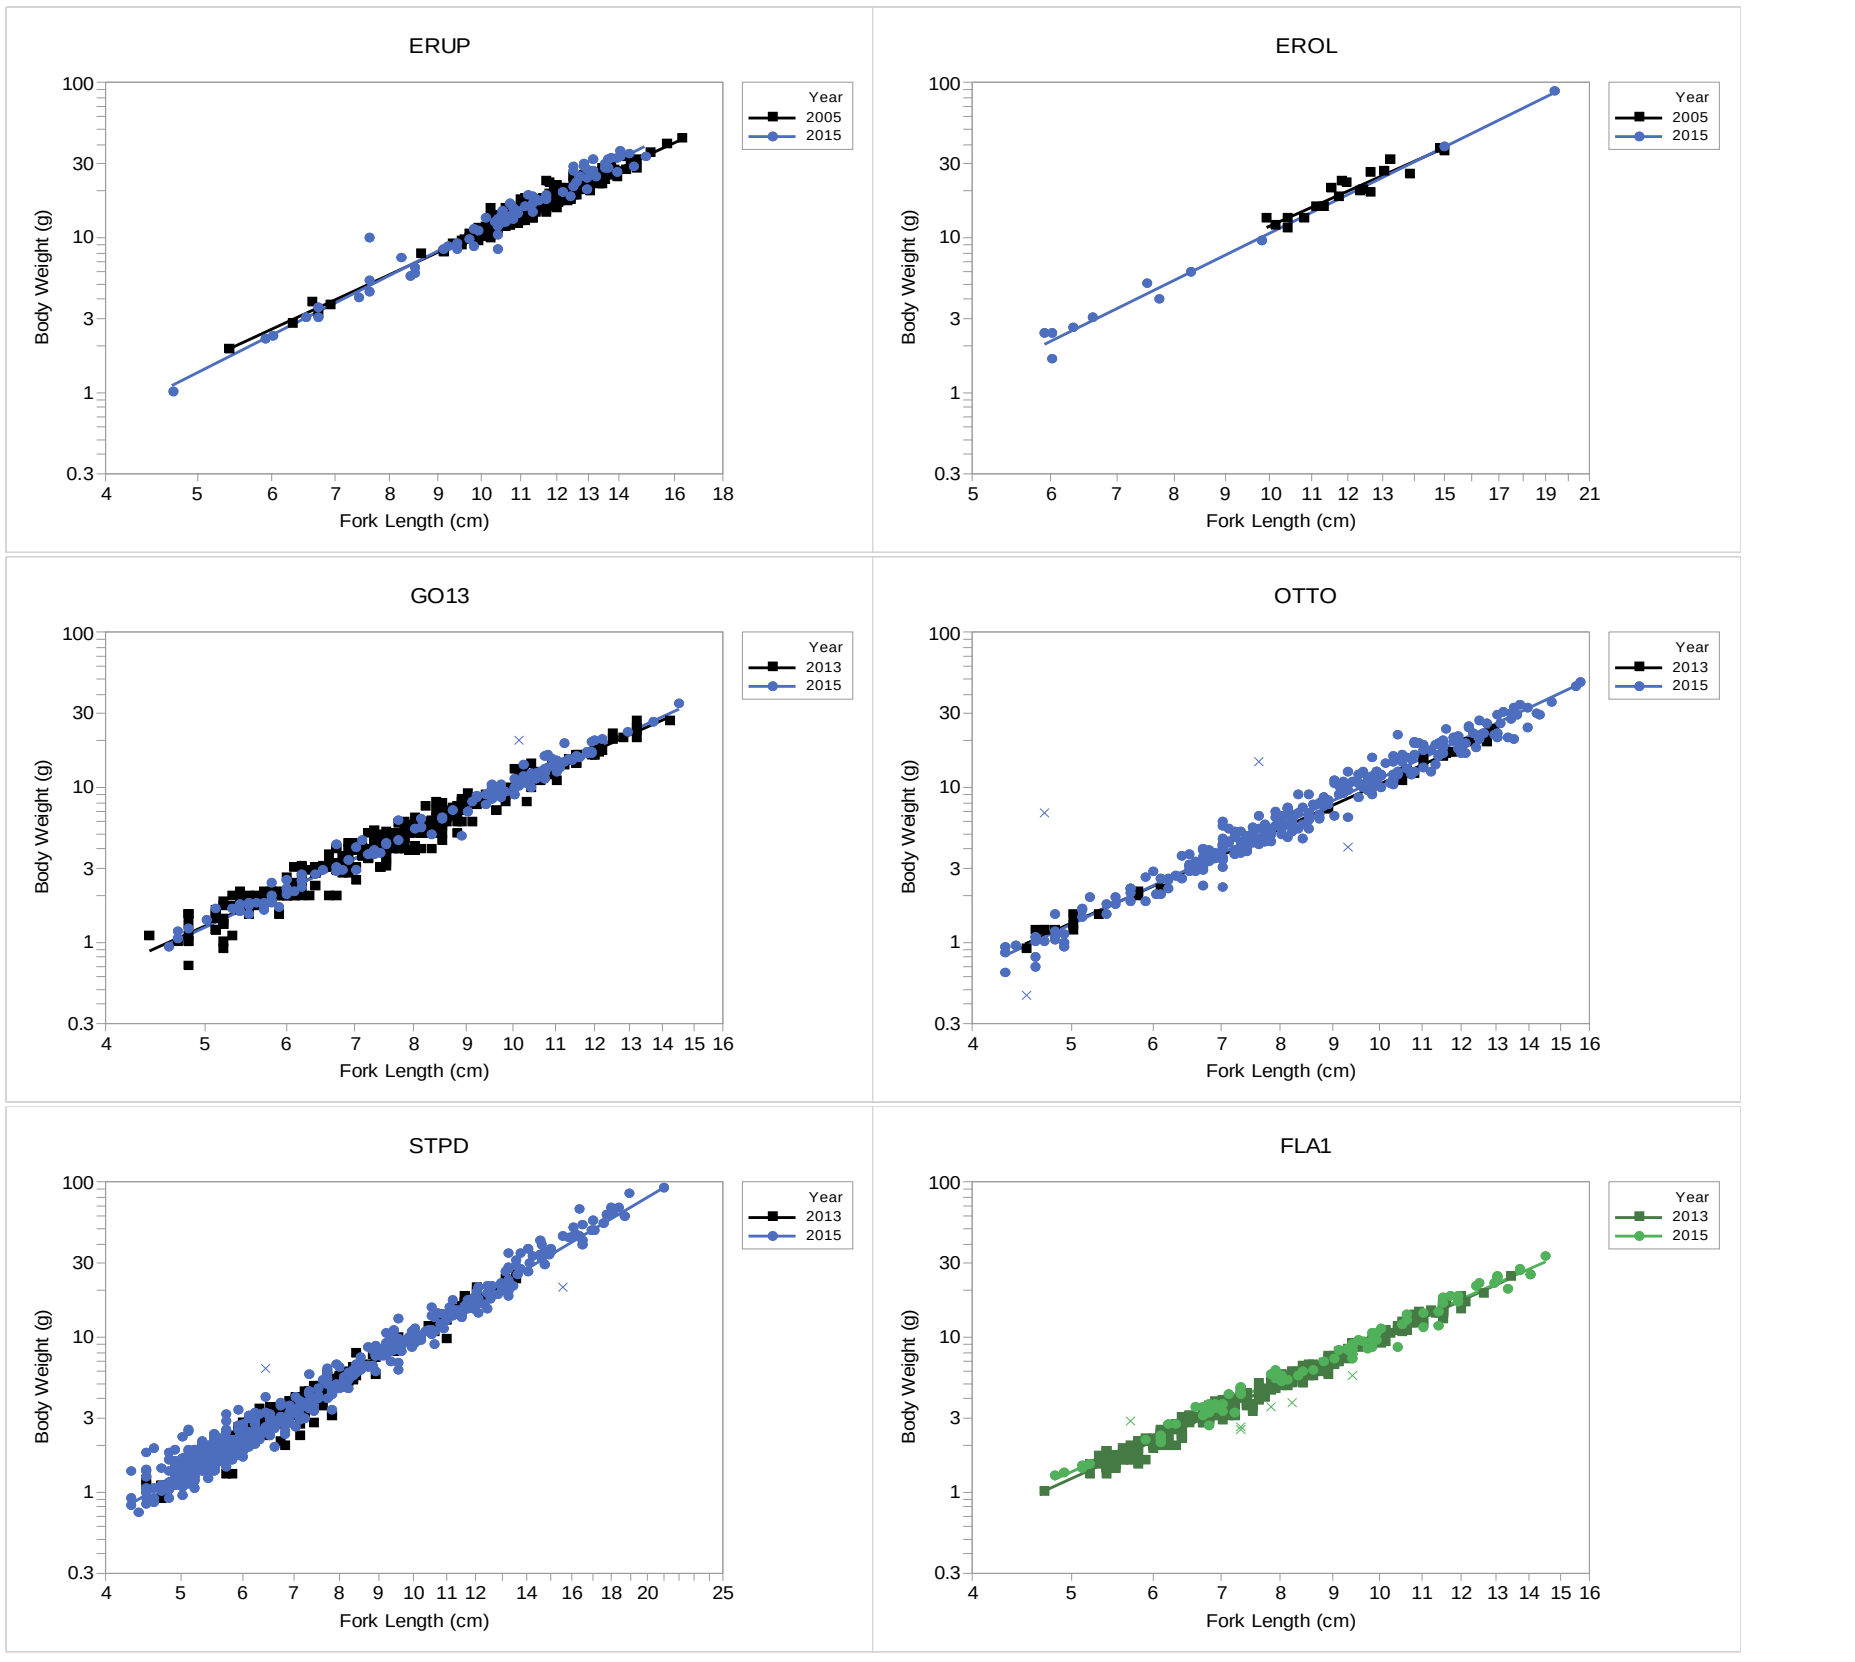

Figure HLSU.7: Scatterplots and Linear Regressions of Body Weight versus Fork Length for Longnose Sucker Collected in 2005 or 2013 Compared to 2015 by Area

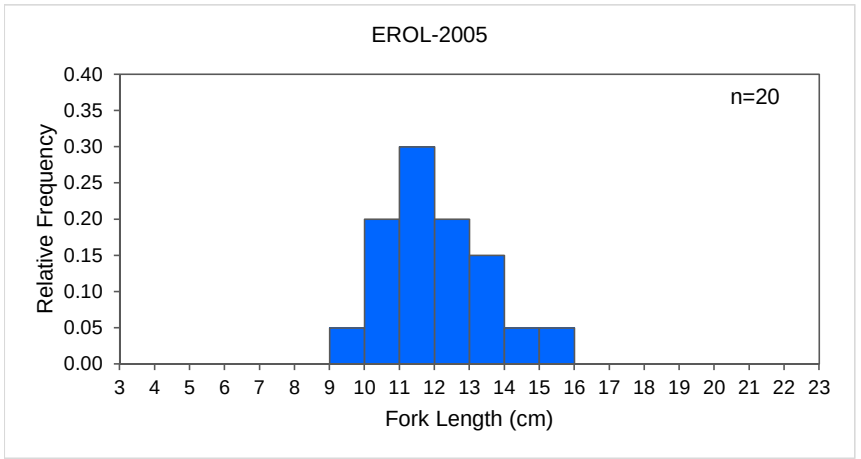
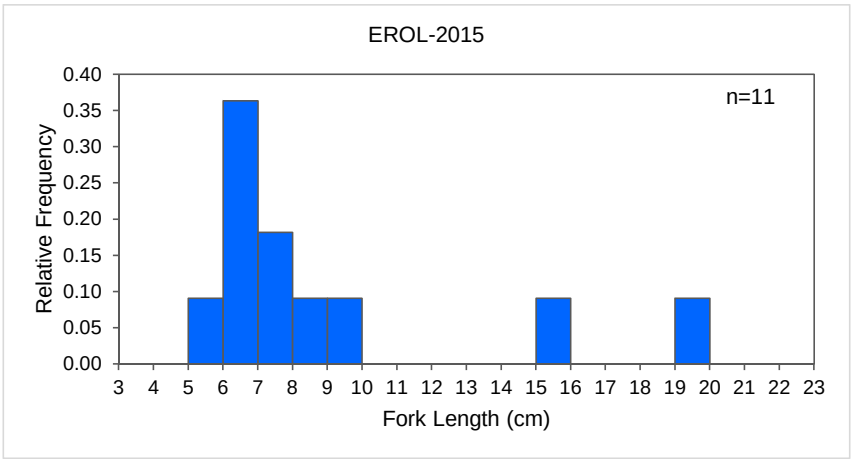
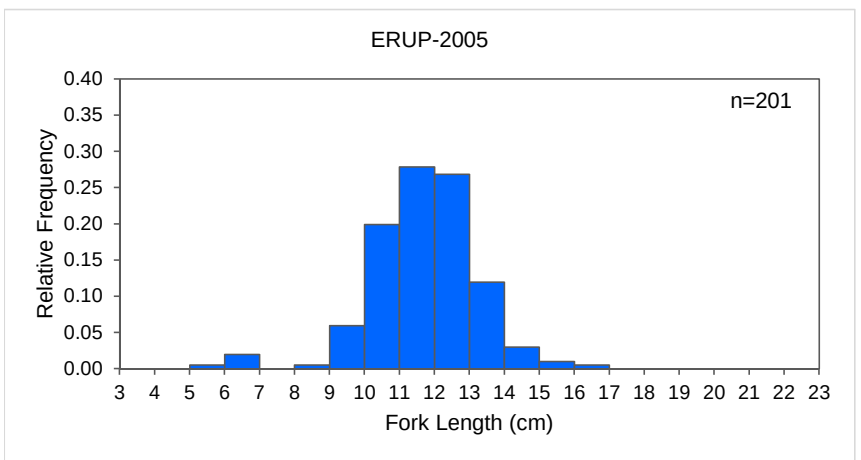
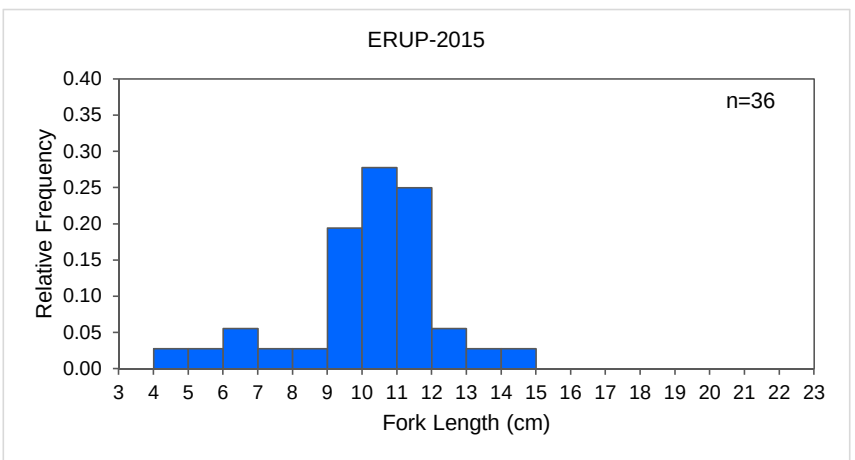
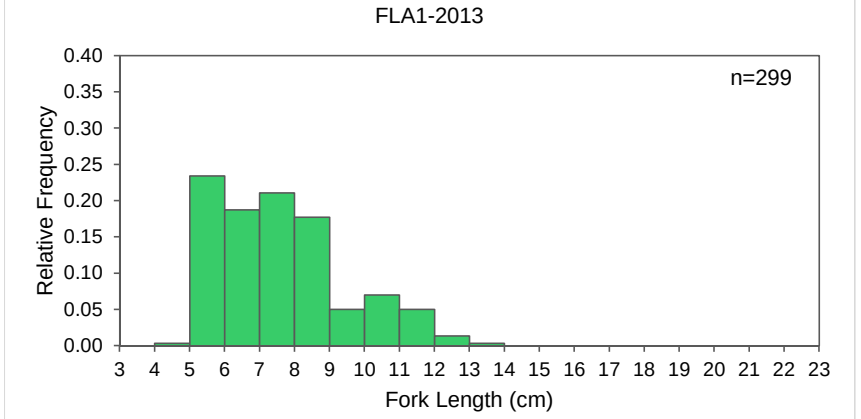
Notes: Outliers removed from statistical analyses are noted by an ×

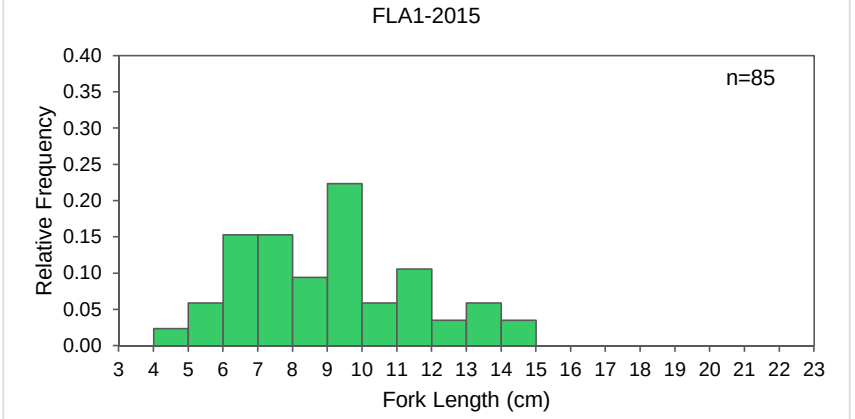


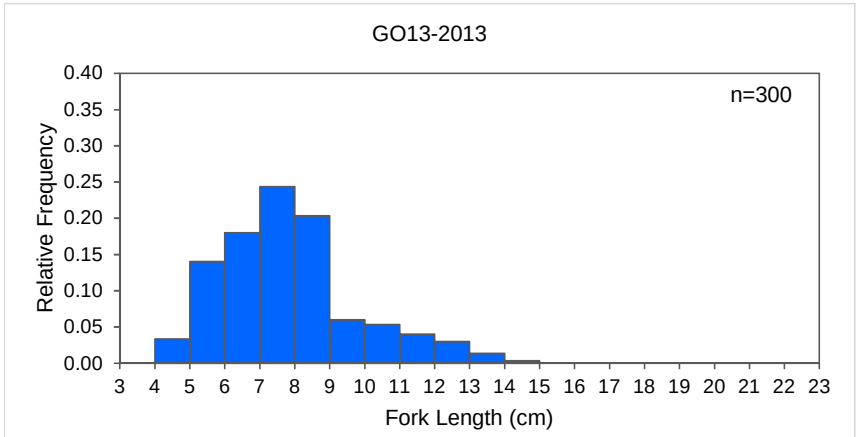


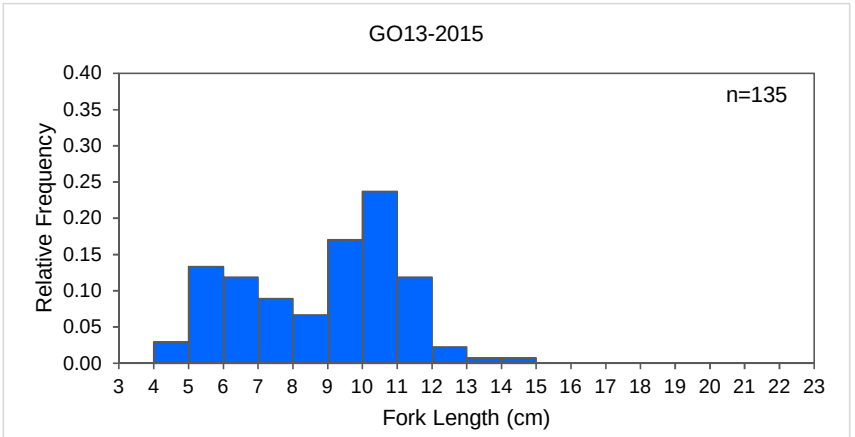


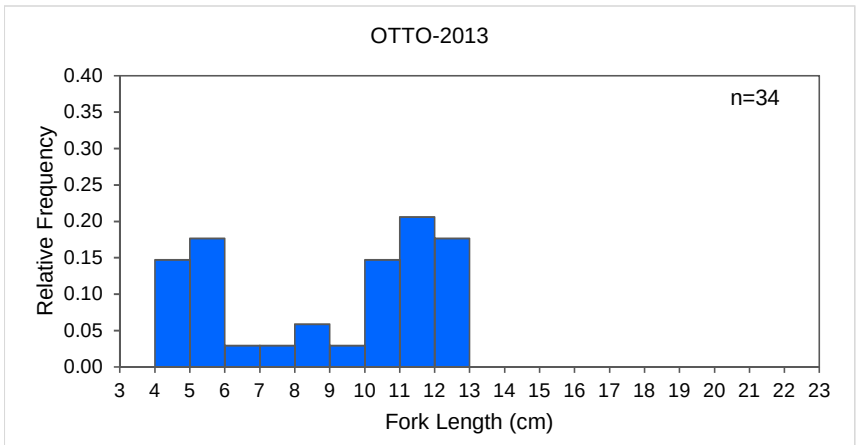


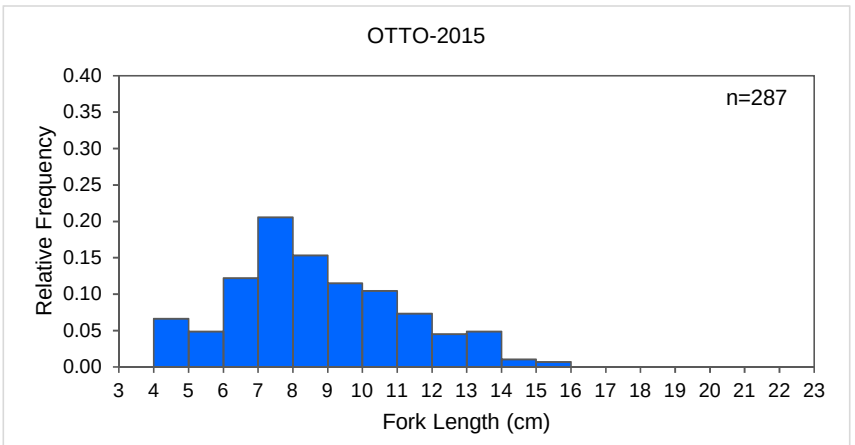


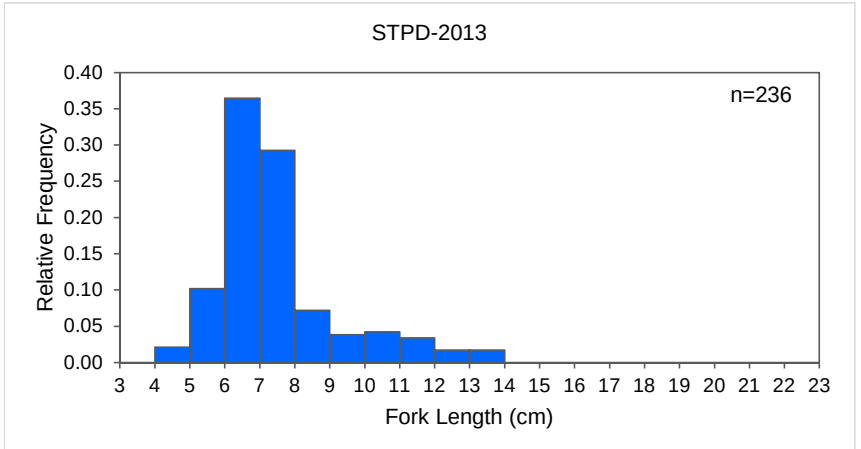












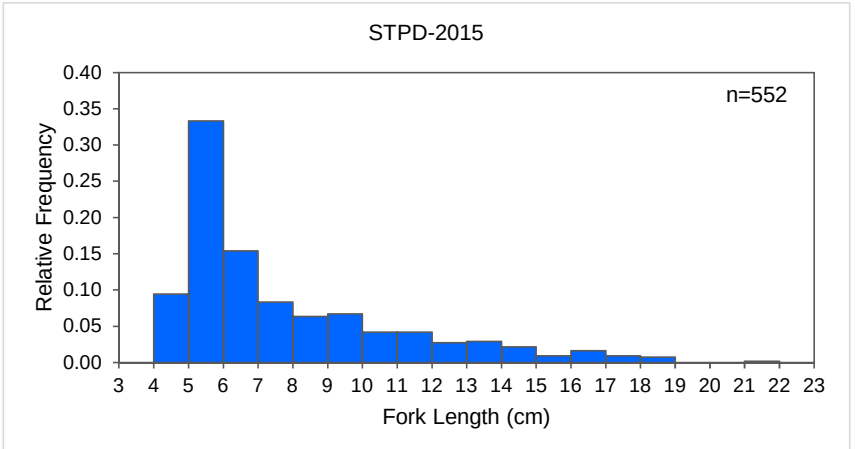


Figure HLSU.8: Length Frequency Distributions for Longnose Sucker by Area and Year for Areas with Two Years of Data (2005 or 2013) and 2015

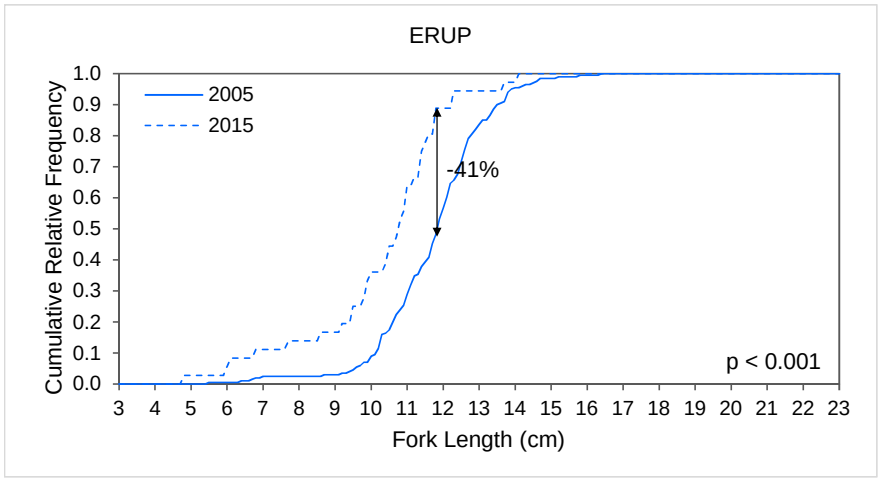

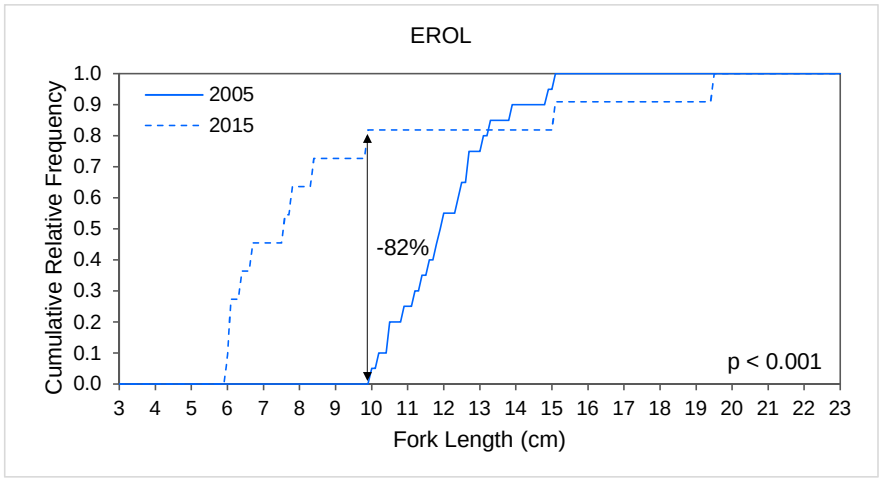

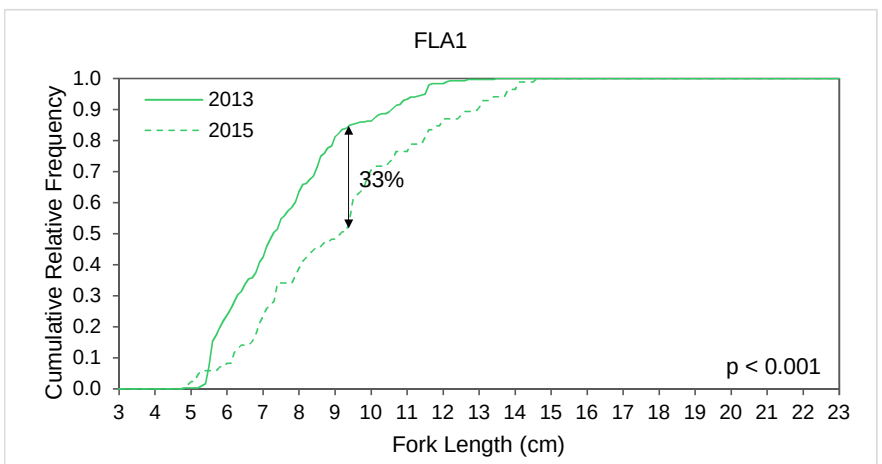

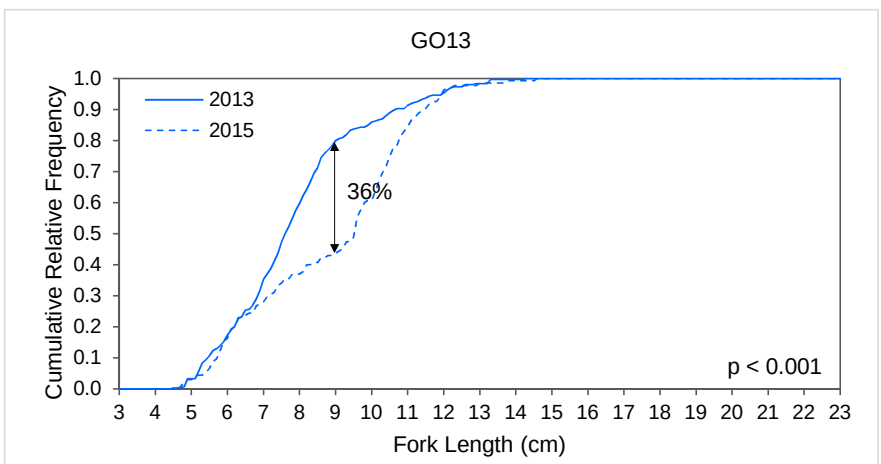

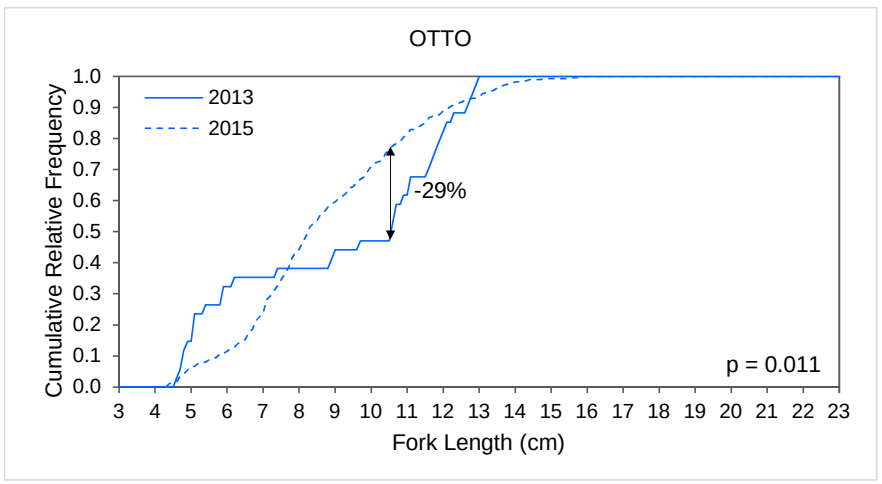

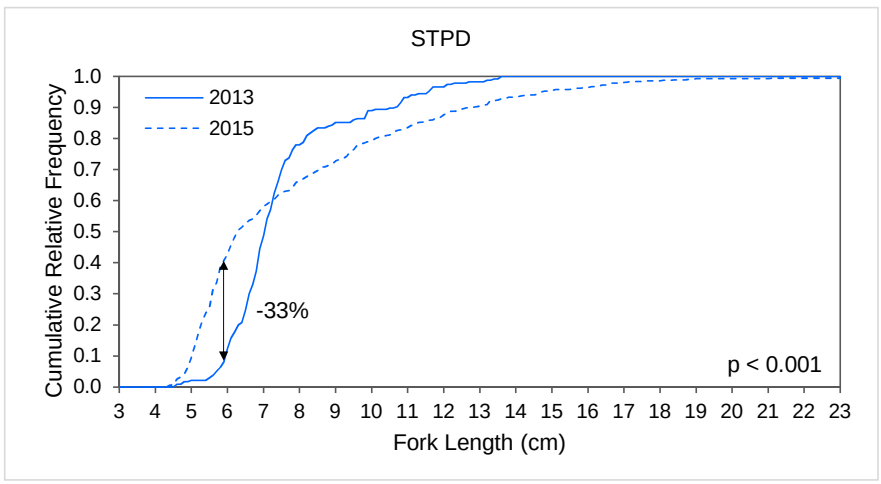

Figure HLSU.9: Cumulative Relative Frequency Distributions for Fork Length of Longnose Sucker for Areas with Two Years of Data Compared with the Two-sample Kolmogorov-Smirnov Test Between Years

Notes: Magnitude of difference = the maximum difference between the cumulative relative frequency distributions. P-value reported for the two-sample Kolmogorov-Smirnov test

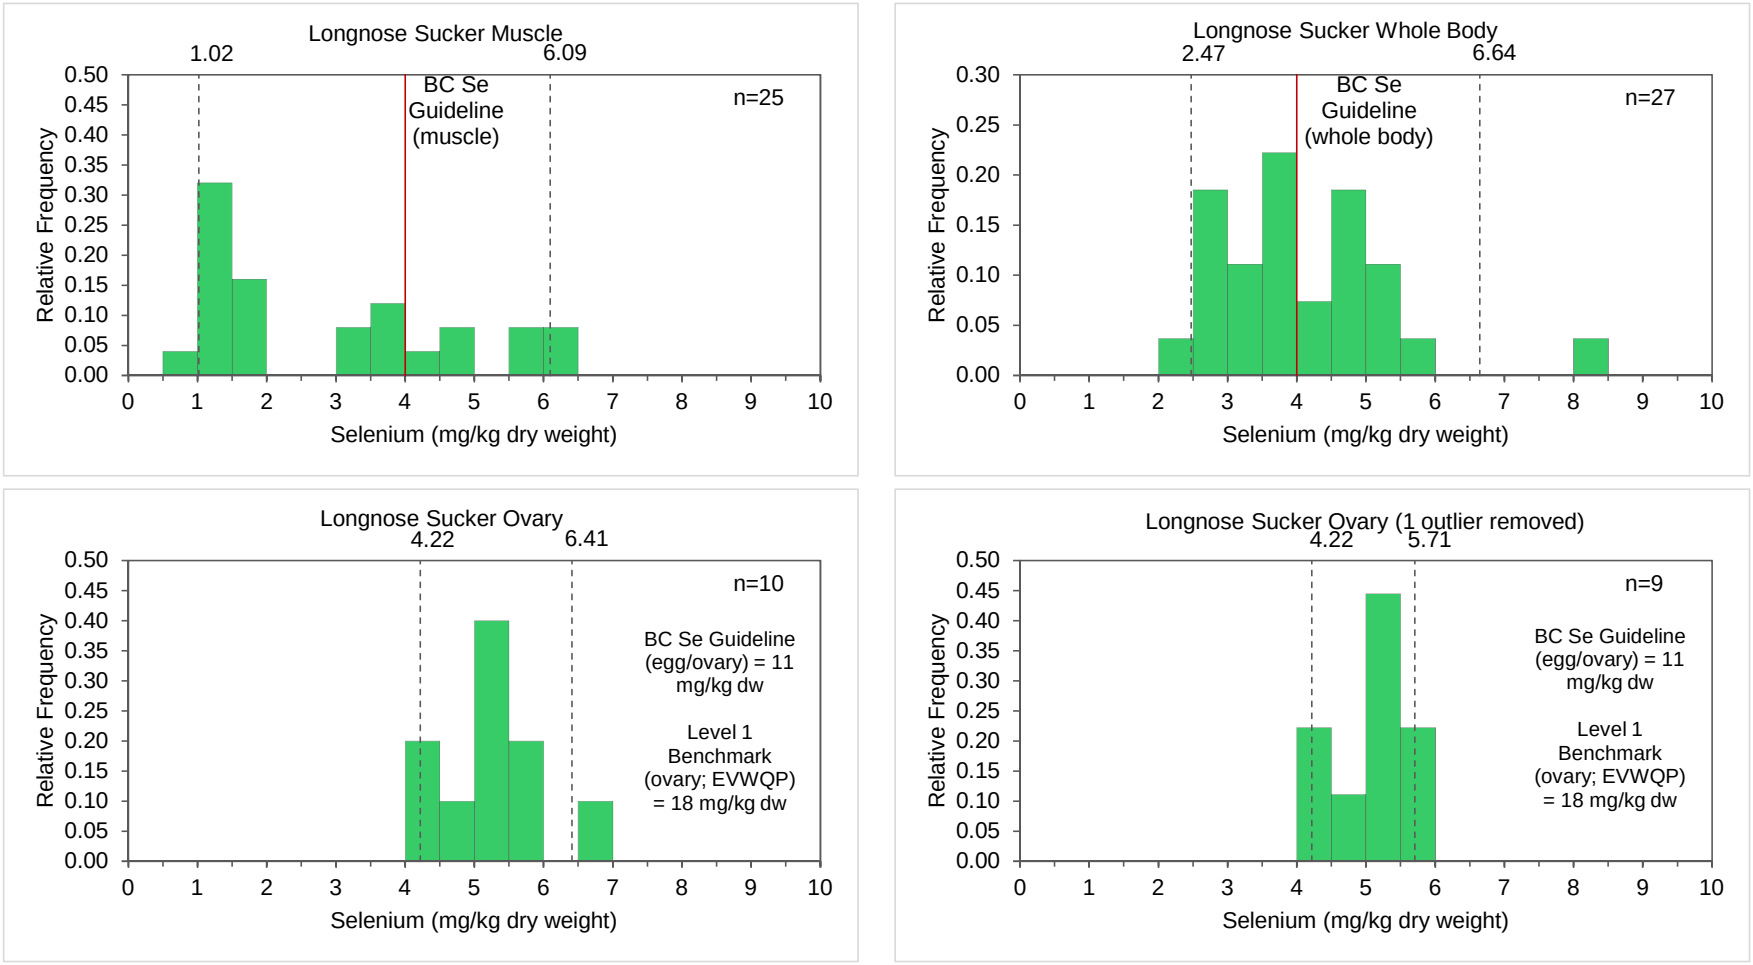

Figure HLSU.10: Distribution of Reference Area Data for Tissue Selenium Concentrations for Longnose Sucker (LSU) in the Elk Valley, 2002 - 2015

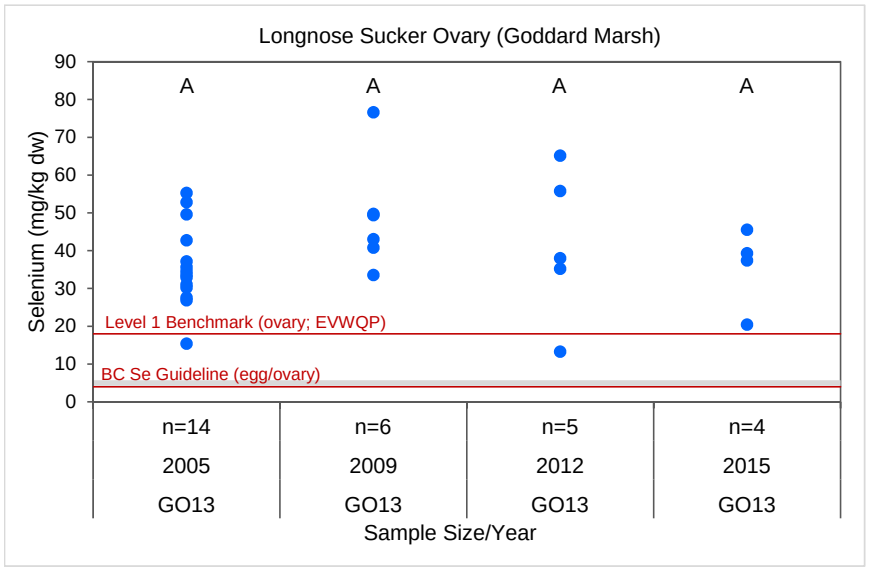
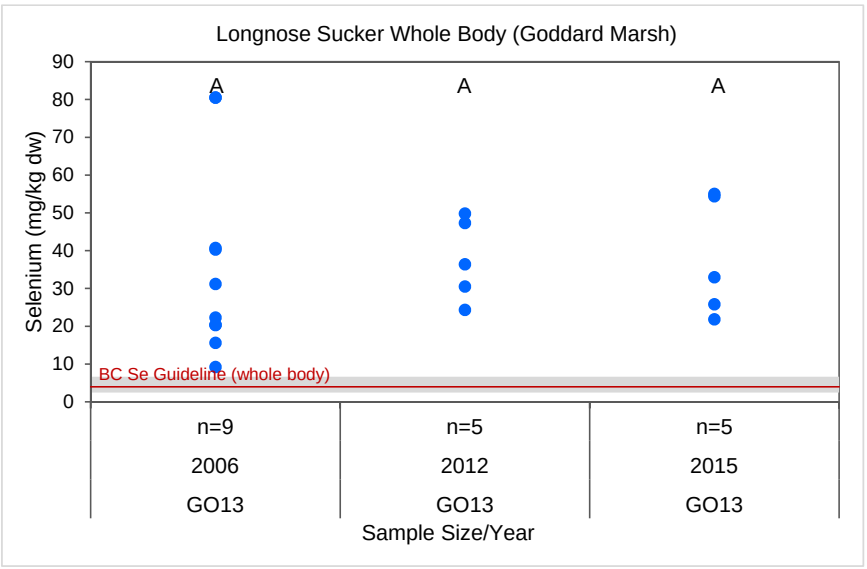
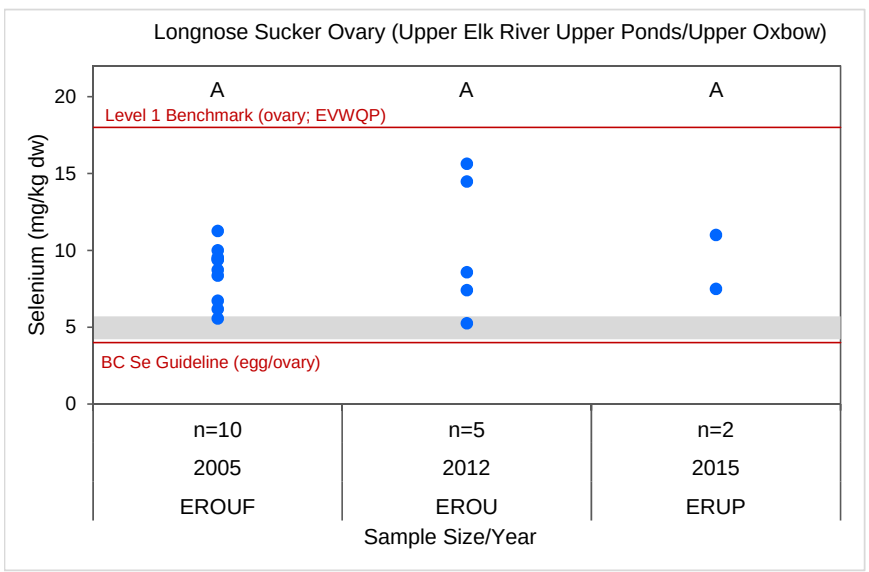
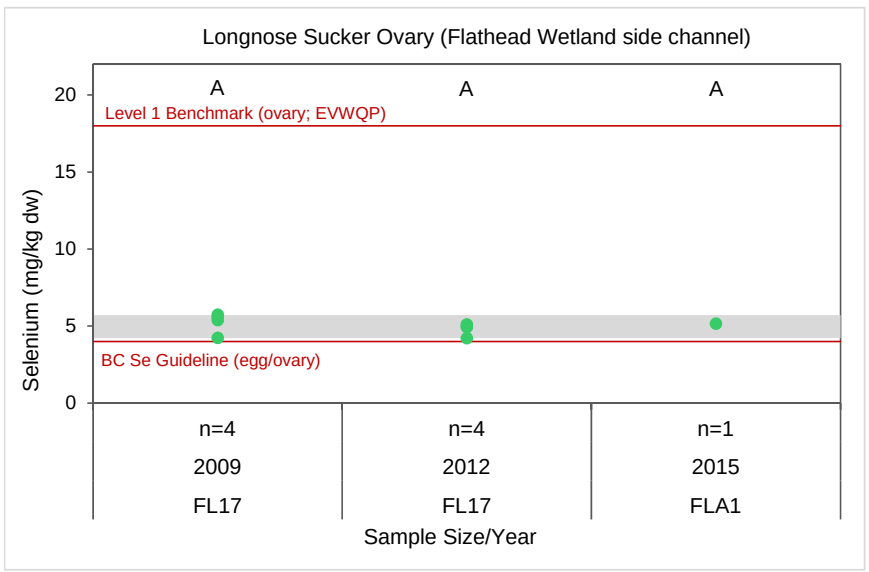
Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles









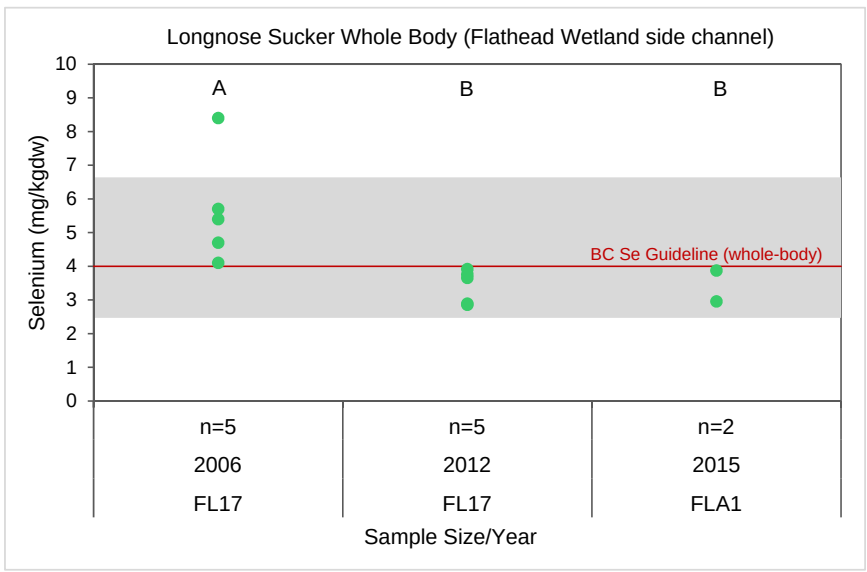


Figure HLSU.11: Individual Value Plot for Selenium Concentrations in Ovary and Whole Body of Longnose Sucker Over Time

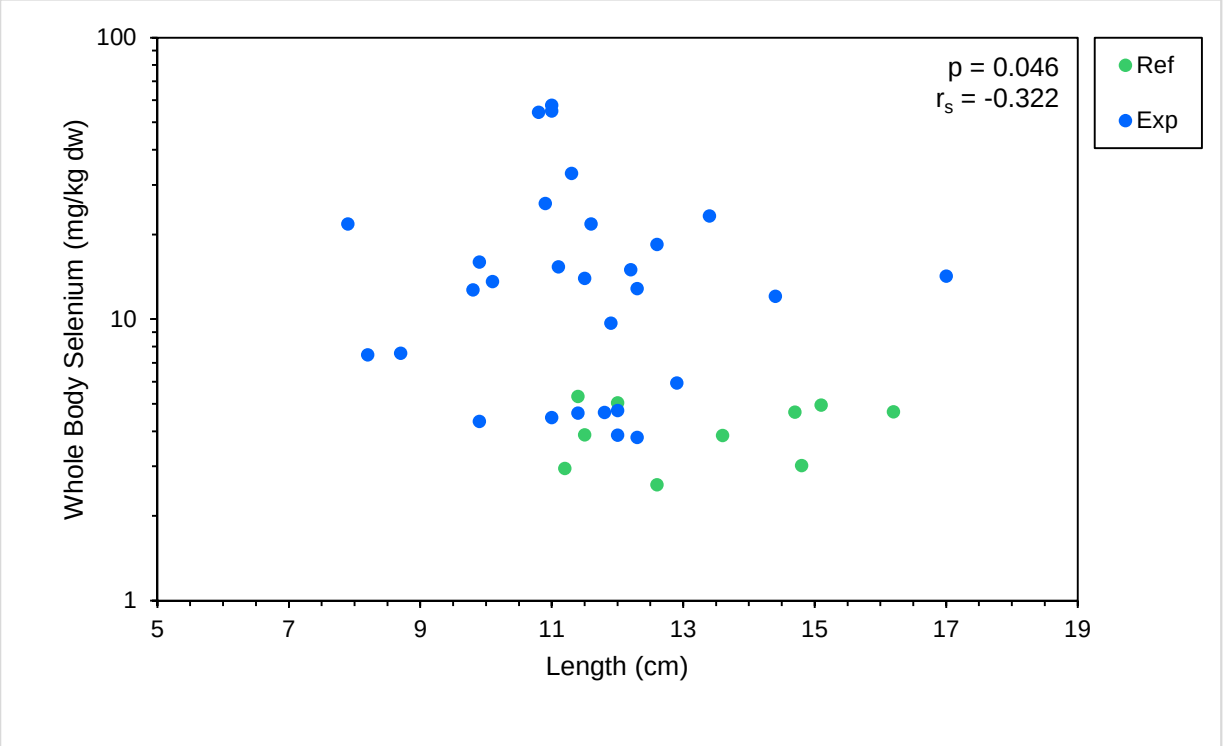
Notes: Time periods that do not share a letter (A or B) are significantly different (p-value < 0.05); reference areas plotted with green symbols



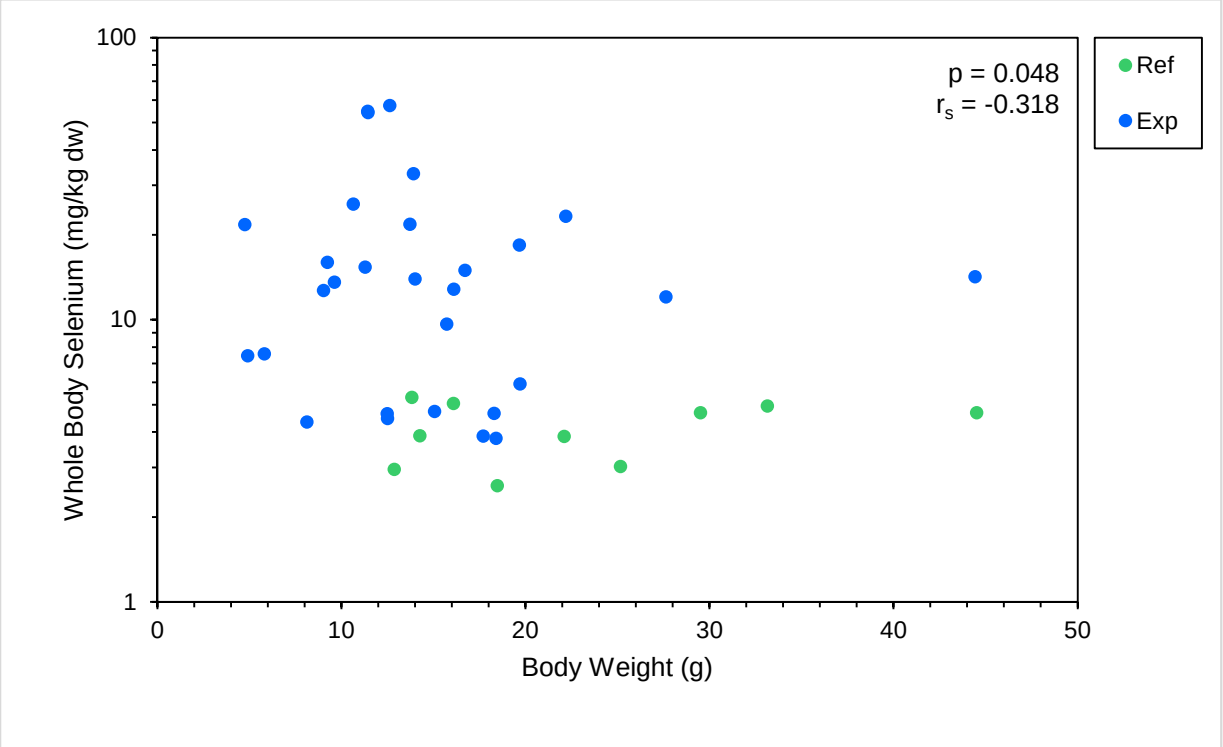


Figure HLSU.12: Spearman Correlations for Longnose Sucker Health Metrics (Length and Body Weight) and Whole Body Selenium Concentrations, 2015

Table HLSU.1: Longnose Sucker Tissue Sampling and Population Monitoring Areas in 2015, and Concordance with Location Codes used in Previous Regional Sampling Cycles

[a] I - Immature, F - Female, M- Male.

[b] An age of 0 denotes fish hatched the previous season that are approaching but are not yet 1 year old.

Notes:

= P-value < 0.05 for ANCOVA interaction covariate term and and P-value < 0.1 for overall test and *post-hoc* comparisons.

n/a = not applicable

[a] Adjusted to preserve a family-wise error rate of 0.1 [Dunnett's method for comparison to a single control for ANOVA/ANCOVA, and Dunn's Test (with Bonferroni correction) for K-W test].

[b] Calculated as the difference in measure of central tendency (MCT) between areas (mine-exposed minus reference), expressed as a percentage of the reference area MCT (except for the K-S test; see footnote c)

[c] Calculated as the maximum difference in the cumulative relative frequency distributions (CRFD; see Appendix Figure HLSU.6) between areas. A negative difference implies that the mine-exposed area has more fish less than the length where the maximum difference in CFRDs was observed. A positive difference implies that the mine-exposed area has fewer fish less than the length where the maximum difference in CFRDs was observed.

[d] The R^2 of the interaction model was 0.9903 and the R^2 of the parallel slope model was 0.9899 (difference of 0.04%) so the ANCOVA proceeded under the assumption that the slopes are practically parallel, as per Environment Canada (2012b) guidance.

[e] Outliers with a Studentized residual with magnitude greater than 4 were removed.

[f] The R^2 of the interaction model was 0.9927 and the R^2 of the parallel slope model was 0.9923 (difference of 0.04%) so the ANCOVA proceeded under the assumption that the slopes are practically parallel, as per Environment Canada (2012b) guidance.

Table HLSU.9: Temporal Comparison of Longnose Sucker Condition by Area for September 2015, Relative to May 2015

Endpoint	Variables		Biological Area Code	Sample Size		Test	ANCOVA Statistics								
							Interaction Model		Parallel Slope Model						
	Response	Covariate		May	Sept		Interaction P-value	R^2	Covariate P-value	R^2	Covariate Value for Comparisons [Fork Length (cm)]	Adjusted Mean [Body Weight (g)]		Month	
												May	Sept	P-value	% Difference Sept Relative to May
Condition	Log_{10} [Body Weight (g)]	Log_{10} [Fork Length (cm)]	STPD	139	411	ANCOVA	<0.001[a]	0.9784	<0.001	0.9778	7.17	3.75	3.84	0.132	2.4
			OTTO	90	193	ANCOVA	0.001[a]	0.9719	<0.001	0.9707	8.37	6.55	6.65	0.454	1.6
			GO13	93	40	ANCOVA	0.164	0.9878	<0.001	0.9876	8.43	6.18	6.29	0.486	1.9
			ERUP	36	43	ANCOVA	0.516	0.9642	<0.001	0.9763	10.72	13.87	13.91	0.934	0.23

[a] The difference in the coefficient of determination (R^2) between the interaction model and parallel slope model is <2% so the ANCOVA proceeded under the assumption that the slopes were equal

P-value < 0.05

Table HLSU.10: Temporal Comparison of Longnose Sucker Condition by Area for May and September 2015, Relative to 2005 or 2013

Endpoint	Variables		Baseline Year	Biological Area Code	Sample Size		Test	ANCOVA Statistics								
								Interaction Model		Parallel Slope Model						
	Response	Covariate			Baseline	2015		Interaction P-value	R^2	Covariate P-value	R^2	Covariate Value for Comparisons [Fork Length (cm)]	Adjusted Mean [Body Weight (g)]		Year	
													2005	2015	P-value	% Difference 2015 Relative to Baseline

FISH

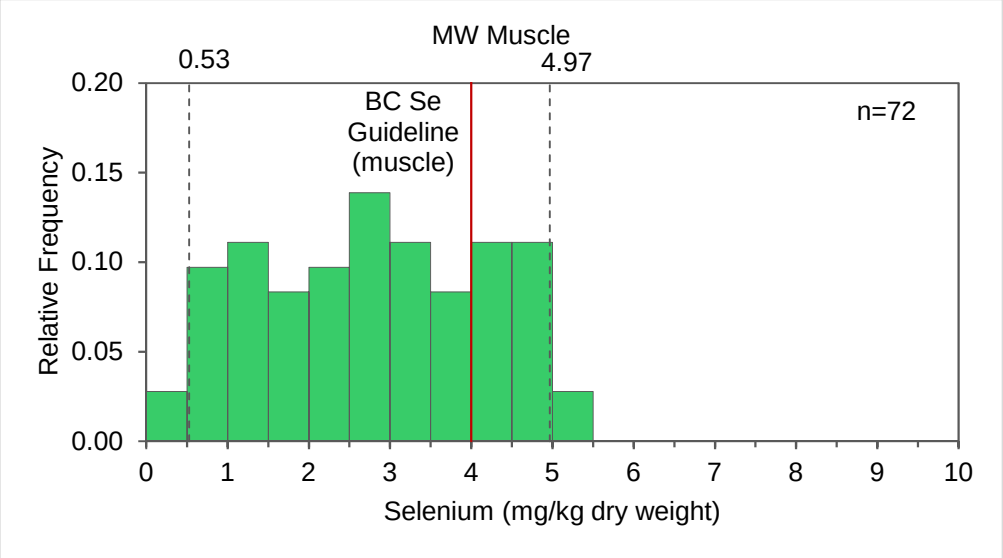
Mountain Whitefish



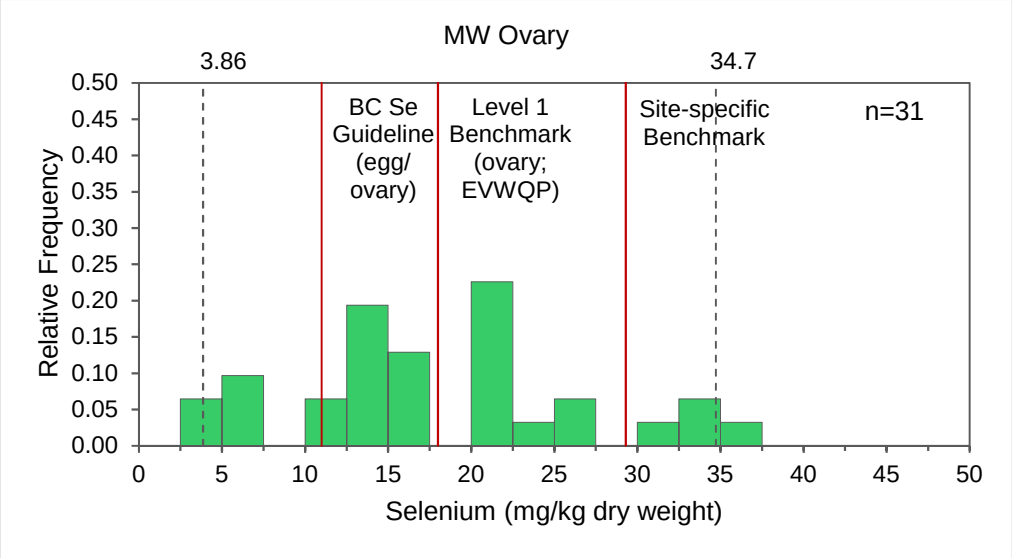


Figure HMW.1: Distribution of Reference Area Data for Tissue Selenium Concentrations for Mountain Whitefish (MW) in the Elk Valley, 2008 - 2015

Notes: Dashed vertical lines represent the 2.5th and 97.5th percentiles

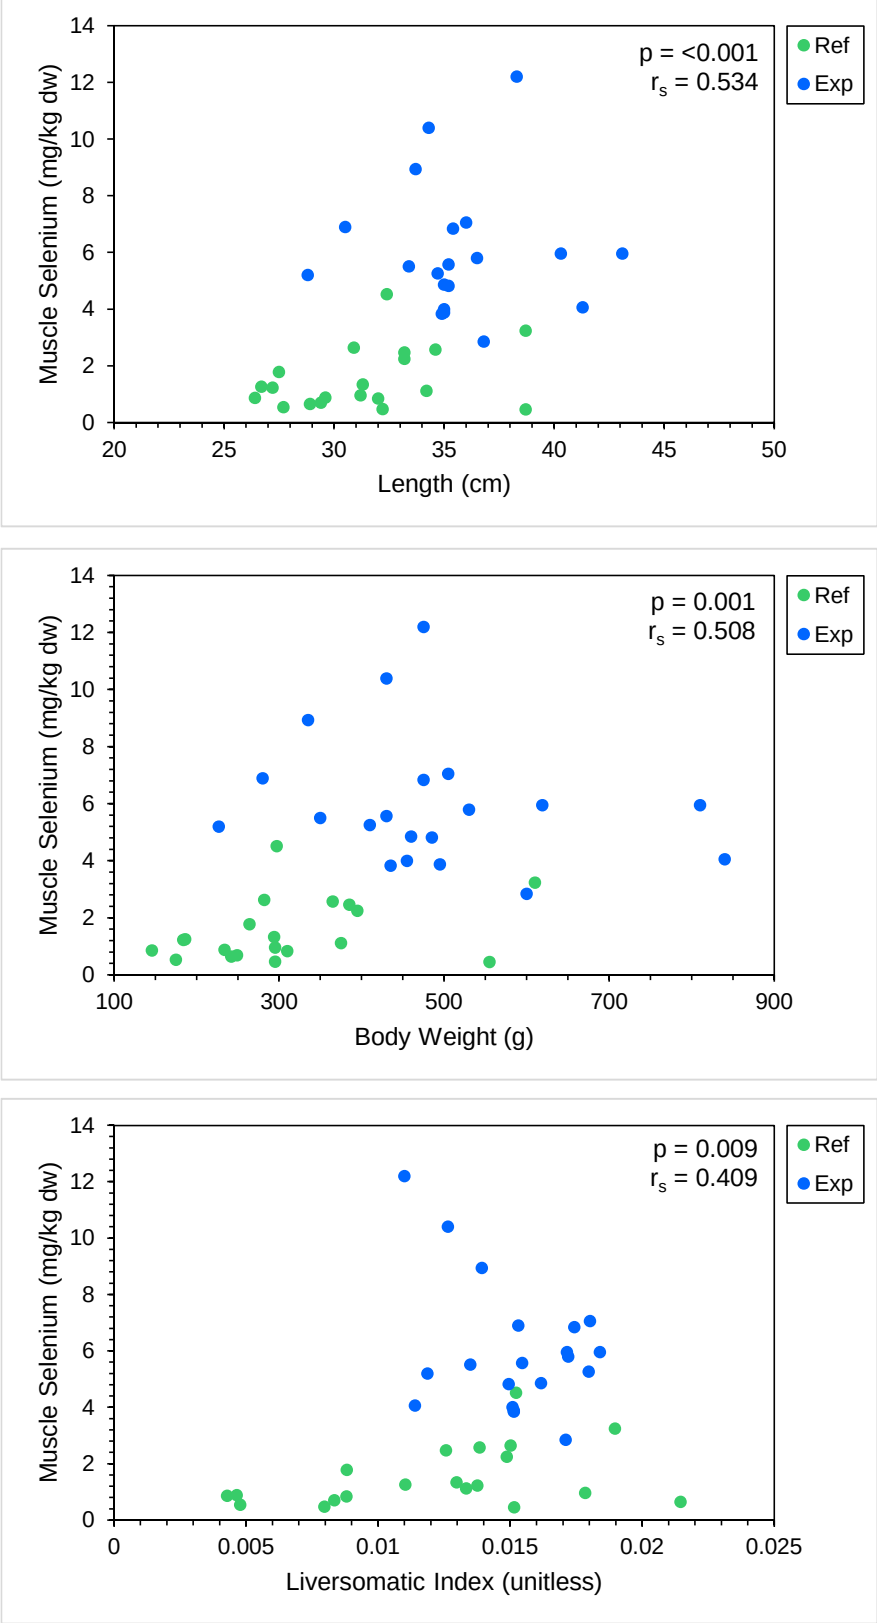

Figure HMW.2: Spearman Correlations for Mountain Whitefish Health Metrics (Length, Body Weight, and Liversomatic Index) and Muscle Selenium Concentrations, 2015

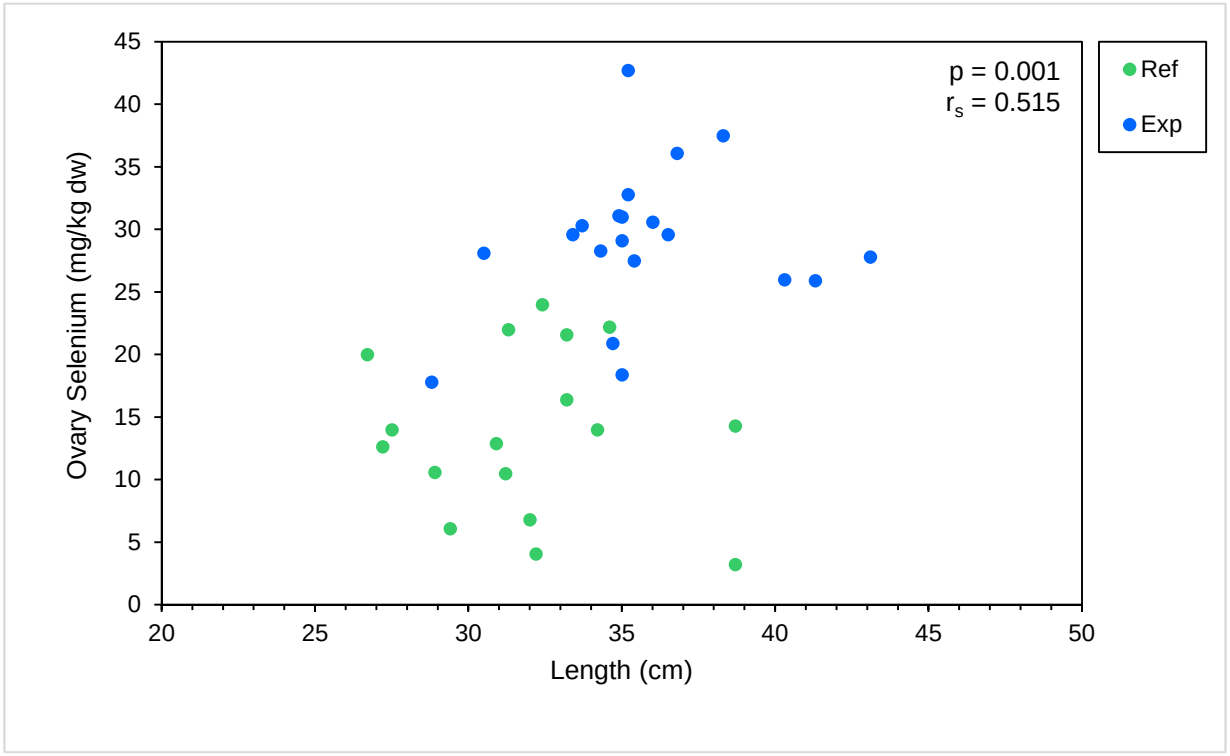

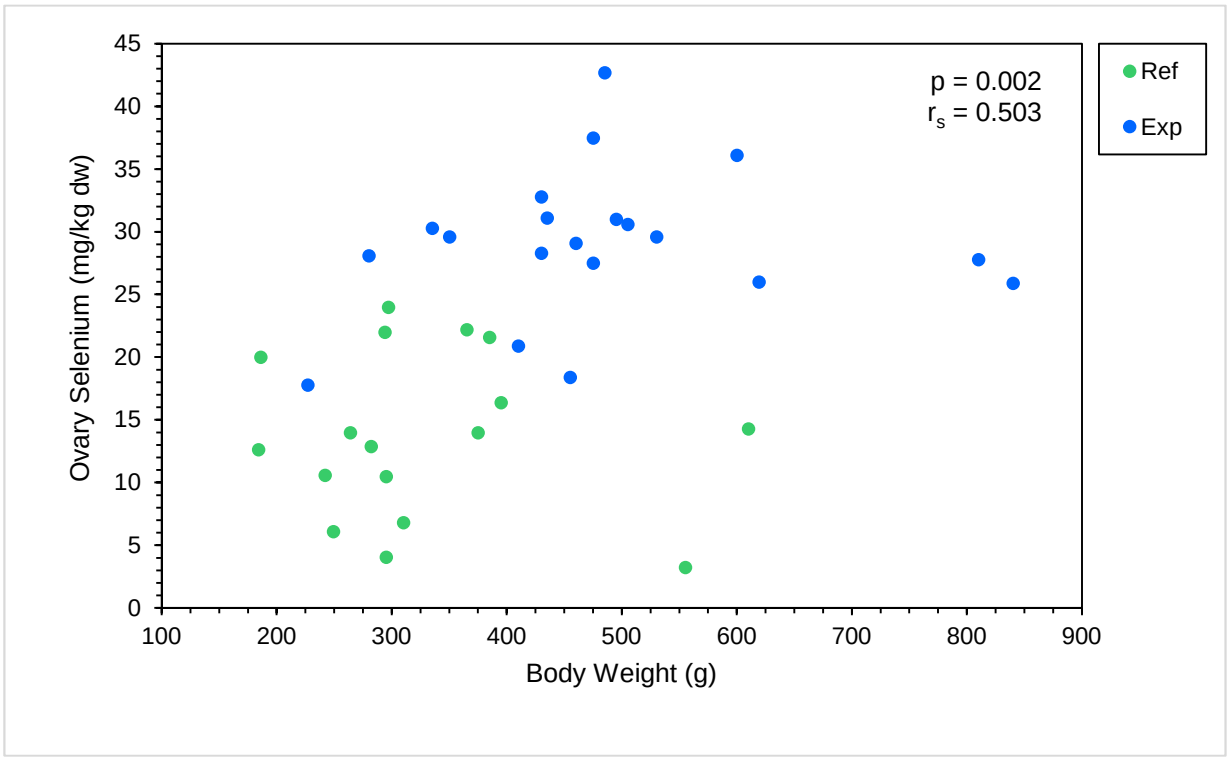

Figure HMW.3: Spearman Correlations for Mountain Whitefish Health Metrics (Length and Body Weight) and Ovary Selenium Concentrations, 2015

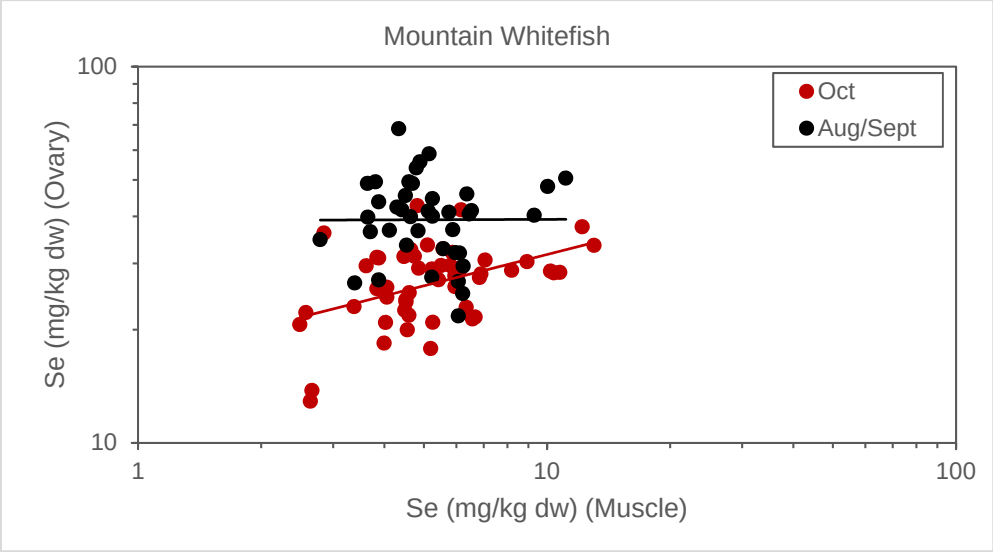

Figure HMW.4: Scatterplot and Linear Regression of Selenium Concentrations in Ovary versus Selenium Concentrations in Muscle for Mountain Whitefish Sampled August and Early September (2006, 2009), and October (2012, 2015)

Notes: Observations with small values of Se (< 2 mg/kg dw) in muscle were removed from the Oct data set to provide equal spread of values muscle Se concentrations between groups; one outlier (3.88, 6.81) was also removed from the Oct group. Slopes are not significantly different ($p = 0.086$); intercepts are significantly different ($p < 0.001$).

Table HMW.1: Mountain Whitefish Tissue Sampling Areas in 2015, and Concordance with Location Codes in Previous Regional Sampling Cycles

[1] PFR - pectoral fin-rays; Oto - otoliths

[2] Whole and (subsample) gonad mass, if gonad was subsampled, the remainder of gonad became part of the carcass weight

[3] Weight of the bag with the carcass: 15.631 g

APPENDIX I
COVARIATE ADJUSTED NORMAL RANGES

APPENDIX I: EVALUATION OF POTENTIAL COVARIATE-ADJUSTED NORMAL RANGES FOR BENTHIC INVERTEBRATE AND PERIPHYTON COMMUNITIES

This appendix presents results for the evaluation of habitat variables as covariates for benthic invertebrate and periphyton community endpoints associated with the 2015 monitoring cycle of Teck's regional aquatic effects monitoring program (RAEMP). This analysis was requested by the EMC.

The evaluation involved selecting habitat variables and conducting multiple linear regressions for key benthic invertebrate and periphyton endpoint (response) and a number of habitat variables (predictors) to derive habitat covariate-adjusted normal ranges. This was done to assess how much variability among reference areas could be explained by natural habitat variation. Community endpoints for mine-exposed areas were compared to the (unadjusted) normal range (defined as the 2.5th and 97.5th percentiles of the pooled (2012 and 2015) reference area data distribution) and the 2.5th and 97.5th percentiles of the residuals from the multiple linear regression (i.e. the covariate-adjusted normal range) to assess whether the addition of one or more covariates increased the sensitivity to detect community differences among mine-exposed areas relative to reference areas. The following bullets briefly explain the series of tables and figures presented in this Appendix I:

- A PCA was conducted with the habitat variables shown in Appendix Table I.1 for all reference areas (n = 36) sampled in 2015[1]. A single habitat variable that was highly correlated with each of the first two principle components was selected to include in the evaluation (Appendix Table I.1). Preference was given to GIS variables, variables that are continuous, and those that do not strongly vary seasonally.
- Appendix Table I.2 shows the multiple regression model statistics for the key benthic invertebrate endpoints with four habitat variables as predictors (two variables identified from the PCA and the squared terms for the two variables) for all reference areas (n = 36) with habitat data in 2015. The squared terms were included to account for non-linearity in the response-covariate relationships. Key benthic invertebrate and

[1] A PCA that included habitat data for mine-exposed gave similar results (Appendix A).

periphyton endpoints were those identified as being correlated with PC-1 for WQ and those identified by the EMC as being important. Variables were log_{10}-transformed when required to meet assumptions of normality of residuals. The model residuals were plotted versus the fitted values to assess homogeneity of variances and outliers (Appendix Figure I.1). Histograms of residuals were assessed (not shown) with model output for a bell-shaped distribution (all distributions appeared approximately bell-shaped).

- Covariate-adjusted normal ranges for each endpoint were defined as 2.5th and 97.5th percentiles of the residuals of the regression models for endpoints that had a significant regression model. The residuals for the mine-exposed areas were calculated using the reference area regression coefficients and compared to the normal range of the reference area regression residuals. Appendix Table I.3 shows the number of mine-exposed areas outside of the reference normal range for each endpoint.
- Appendix Table I.4 shows how strongly (or not) each of the endpoints (model residuals) correlated with the first Principal Component (PC-1) for water quality, which reflected a gradient of mine-related influence. Appendix Table I.4 includes three new versions of PCA: (1) PCA based on (1) hazard quotients (HQ) for all WQ variables with a benchmark and calcite index, (2) PCA based on concentrations of only selenium, nitrate, and sulphate in water and calcite index; and (3) PCA based on hazard quotients (HQ) for selenium, nitrate, sulphate, and calcite (PCA details are in Appendix Table G.6).
- Appendix Table I.5 presents a summary of the normal range comparisons based on (1) 2.5th and 97.5th percentiles of model residuals; (2) the 2.5th and 97.5th percentiles of the pooled (2012 and 2015) reference area data distribution with all observations; and (3) the 2.5th and 97.5th percentiles of the pooled (2012 and 2015) reference area data distribution with outliers removed (see Appendices F and G). In general the two methods identified similar areas being outside of normal. Some differences were observed for LPL Richness (11 additional areas identified < the lower limit of the normal range) and % *Achnanthidium* (6 additional areas identified above the upper limit of the normal range) but these do not appear to be related to mining (lack of correlation with PC-1 and comparisons to other endpoints in Table I.3).
- Appendix Table I.6 shows a subset of the endpoints from Appendix Table I.5 (those endpoints that are significantly correlated with PC-1 for water quality (Appendix Table I.4) as well as hazard quotients for key mine related water quality variables. The objective here was to assess whether the additional mine-exposed areas that are outside of the normal range for %EPT were areas that may be predicted to be affected

(based on hazard quotients), which they were not (HQs near or below 1 for these areas).

- It is difficult to visualize the regression residual approach to define the NR because the relationship between a single benthic invertebrate endpoint and six predictor variables cannot be plotted.
- Overall, the evaluation indicated that covariate-adjusting normal ranges yields insufficient benefit to warrant applying such a complex method. After discussion of results with the EMC it was agreed that normal ranges will be defined without covariate adjustment.

EXECUTIVE SUMMARY

Background

Teck Resources Limited (Teck) owns and operates five metallurgical coal mines within the Elk River watershed in southeastern British Columbia (BC). Mine discharges report to the Elk River which flows into Koocanusa Reservoir. Koocanusa Reservoir was created when the Libby Dam (Montana) was constructed in 1972, and is operated by the United States Army Corps of Engineers to provide flood control, hydroelectric power, and recreational opportunities. The reservoir straddles the border between Canada and United States, and lies within the traditional territory of the Ktunaxa First Nation. At full pool, about 68 km of the total 155 km length of the reservoir is in BC. Three Canadian rivers, the Kootenay (62% of mean annual inflow), Elk (26%), and Bull (11%), supply most of the reservoir's inflow. Water levels are managed at the Libby Dam, and are generally lowest in late winter or early spring and highest in summer/early fall. Normal annual pool fluctuation is about 35 m. At maximum drawdown, the reservoir volume is reduced by up to 85%, mean depth by 51%, surface area by 69%, and total length by 53%, with the largest relative changes occurring in the Canadian portion of the reservoir. Mean residence time is 0.55 years.

Discharges from Teck's metallurgical coal mines to the Elk River watershed are authorized by the BC Ministry of Environment (MOE) through permits that are issued under provisions of the *Environmental Management Act.* Permit 107517, which specifies the terms and conditions associated with those discharges, was issued November 19, 2015 and was recently amended on June 5, 2017, which included requirements for monitoring in Koocanusa Reservoir. A three-year study was implemented from 2014 to 2016 to characterize and compare chemical and biological conditions in the reservoir downstream from the Elk River compared to upstream. This report presents results of the monitoring completed within the Canadian portion of the reservoir.

Water Quality

In situ profiles taken in February, April, and/or August showed only limited temperature, oxygen, pH, and conductivity gradients with depth. Most of the water column was oxygenated with slightly alkaline pH. A previous study concluded that waters in the Canadian portion of the reservoir remain relatively well-mixed, even during periods of maximum water elevation (May-November), as a result of basin morphometry, continual movement of water from river inputs and reservoir operations, and exposure to strong prevailing winds.

As the purpose of this study was to identify potential influences on Koocanusa Reservoir related to metallurgical coal mining inputs to the Elk River, the evaluation of water quality focused on

substances associated with metallurgical coal mining: nitrate, selenium, and sulphate. Statistical tests showed that concentrations of these substances were similar in water samples collected at middle and bottom depths at all downstream sample locations, but differed from concentrations measured in samples collected at the surface. At the stations in the reservoir downstream from the Elk River, nitrate, selenium, and sulphate concentrations were typically lower at surface sampling depths. Differences between upstream and downstream concentrations were greater in 2016 than 2015 for both nitrate and selenium, but mean concentrations at the downstream areas in 2016 were similar to or less than those observed in 2015. Sulphate concentrations did not differ significantly between Koocanusa Reservoir stations located downstream versus upstream of the Elk River in any years.

With the exception of aluminum (one sample at RG_DSELK in 2015), iron (one sample at RG_GRASMERE in 2015 and one sample at RG_DSELK in 2016), and mercury (5 samples at RG_DSELK in 2016), water quality guidelines were not exceeded in water samples collected at stations throughout the reservoir as part of Teck's routine water quality monitoring program. Site performance objectives for nitrate, selenium, sulphate, and dissolved cadmium were consistently met at the station downstream from the Elk River.

Sediment Quality

Sediment samples collected in the reservoir both downstream and upstream from the Elk River were mostly silt (≥60%), with sand and clay comprising smaller fractions. Sediments collected along a transect upstream from the Elk River (T2/TN) were significantly sandier (annual means of 2-10%) with less clay (means of 17-19%) than those collected at a downstream transect (T4; means of <1% for sand and 26-30% for clay). This may be related to the shallower depths and more fluvial nature of the reservoir at T2/TN (i.e., greater seasonal scour resulting in finer particles accumulating in sediments farther downstream). Total organic carbon content was consistent at both areas, ranging from 0.9 to 1.7%.

Concentrations of most metals and polycyclic aromatic hydrocarbons (PAHs) in sediment were higher in sediments collected downstream from the Elk River compared to upstream, but did not increase over the three year study. Concentrations of some metals (upstream and downstream) and PAHs (downstream only) in sediments were above the lower provincial sediment quality guidelines, but none exceeded the higher guidelines. The general pattern of higher concentrations in sediment downstream from the Elk River compared to upstream may be related to a greater proportion of fine sediment particles in the downstream area, providing more surface area for adsorption than larger particles.

Plankton and Productivity

The reservoir is considered to be phosphorus limited. Low concentrations of phosphorus and chlorophyll-a, along with low seston and zooplankton biomass, all indicated that the reservoir is oligotrophic. Phytoplankton communities in the reservoir were numerically dominated by diatoms (algae with cell walls of hydrated silica), and to a lesser extent with Chrysophytes (golden algae). There were no significant differences in overall phytoplankton density, biomass, or richness between downstream and upstream areas over the three years. Community structure was similar between upstream and downstream areas, except for greater Cyanophyte (blue-green algae) biomass at the downstream area, which was considered to have low ecological significance because this group represented <1% of the community. Large year-to-year variation in the percent composition of major algal groups was reported in a previous study based on data collected from 1975 to 1988. Previous study authors concluded that the dominant influence on primary production in Koocanusa Reservoir was light quantity, which is influenced by: a) thermal structure which allows phytoplankton to be circulated out of the euphotic zone, b) turbidity in the inflows during spring runoff (freshet), and c) seasonal and meteorological variations in incident solar radiation.

The zooplankton community in Koocanusa Reservoir was numerically dominated by rotifers and copepods, with relatively low numbers of cladocerans. No consistent differences were observed between downstream and upstream areas in overall zooplankton density, biomass, or richness, or in absolute or relative density or biomass of copepods or rotifers, over the three year study. Abundance and biomass of cladocerans tended to be lower downstream from the Elk River compared to upstream. However, the smaller size of rotifers resulted in a considerably lower relative biomass compared to copepods and cladocerans. Overall community structure, indicated no consistent differences downstream compared to upstream from the Elk River over the three years. Selenium concentrations in zooplankton were similar between downstream and upstream areas in all three years.

Benthic Invertebrates

Benthic invertebrate communities sampled in Koocanusa Reservoir upstream (T2/TN) and downstream (T4) from the Elk River were primarily composed of oligochaetes (mostly immature Tubificinae), insects (various species of chironomids), and ostracods in all three sample years. Total community density ranged from 984 to 3,533 organisms/m^2, which may be low compared to some reservoirs, but comparable to results reported in previous studies for Koocanusa Reservoir. Overall community density and richness did not differ significantly between upstream and downstream areas in any of the three study years. However, community structure differed between areas, particularly with respect to ostracods, which had higher average density at the

downstream area (means ranging from 849 to 1,686 per m^2) compared to the upstream area (means of 38 to 333 per m^2) over the three years of study. Densities of oligochaetes were also significantly higher at the downstream area (range of 1,194 to 1,449 per m^2) compared to the upstream area (range of 418 to 1,194 per m^2). Greater abundance of these organisms downstream from the Elk River compared to upstream may be associated with preference for greater depths and finer sediment texture, and/or avoidance of coarser, compacted sediments in the upstream area that dry out during low pool.

Mean benthic invertebrate tissue selenium concentrations were significantly higher at the downstream area (6.9 µg/g dw) than the upstream area (5.0 µg/g dw), and were greater than the BC interim chronic dietary guideline of 4 µg/g dw, but were consistently less than the Level 1 benchmarks (based on <10% effect) developed in the Elk Valley Water Quality Plan for growth and reproductive effects to benthic invertebrates (13 mg/kg dw) and for dietary effects to fish (11 mg/kg dw).

Fish

Largescale sucker, northern pikeminnow, peamouth chub, redside shiner, and yellow perch were consistently captured in highest numbers at all three study areas (i.e., Sand Creek, Elk River, and Gold Creek) in Koocanusa Reservoir in 2014 to 2016. Other species that were captured included bull trout, burbot, kokanee, longnose sucker, mountain whitefish, pumpkinseed, rainbow trout, slimy sculpin, and westslope cutthroat trout.

Following technical guidance developed by Environment Canada, fish surveys were conducted in April of each study year at three areas (two downstream from the Elk River [Elk River and Gold Creek] and one upstream from the Elk River [Sand Creek]) to assess endpoints indicative of fish survival (mean age), growth (body size-at-age), reproduction (relative gonad weight) and energy storage (relative liver weight and overall condition). Peamouth chub were targeted in 2014 but additional species (northern pikeminnow, redside shiner, yellow perch, and largescale sucker) were also evaluated in subsequent years. Results were statistically compared between the downstream areas and the upstream area. No consistent patterns were observed among fish species, sexes, or sampling years that were indicative of influence from the Elk River.

Tissue samples were collected for analysis of metals from fish species captured in the April surveys, as well as fish collected in February and/or August of each year. Some fish had muscle or whole body concentrations of selenium greater than the BC tissue guidelines of 4 µg/g dw for both tissue types. All muscle and whole body samples were less than the United States Environmental Protection Agency (USEPA) criterion of 11.3 µg/g dw in muscle and 8.5 µg/g dw in whole bodies, except for a single yellow perch with a muscle selenium concentration of 15.0 µg/g dw. Similarly, ovary selenium concentrations were frequently greater

than the BC chronic guideline of 11 µg/g dw (particularly in peamouth chub, redside shiner, and northern pikeminnow). All species except redside shiner and northern pikeminnow had mean ovary selenium concentrations less than the Level 1 benchmark for reproductive effects to fish (18 mg/kg dw), and the 2016 USEPA guideline of 15.1 µg/g dw. Northern pikeminnow had mean ovary selenium concentrations above the Level 1 benchmark at the Elk River area in only one of the three years they were sampled (2014), when ovaries were relatively undeveloped. Mean redside shiner ovary concentrations were above the Level 1 benchmark at both the Elk River and the Sand Creek areas in both years sampled. Exceedances of tissue selenium benchmarks or guidelines does not necessarily mean that effects will occur as fish species show a range of sensitivities to selenium.

Next Steps

These data will be used as the basis for future study design development for a long-term monitoring program.

LIST OF TABLES

1 INTRODUCTION

1.1 Background

Teck Resources Limited (Teck) owns and operates five metallurgical coal mines within the Elk River watershed in southeastern British Columbia (BC; Figure 1.1). Mine discharges report to the Elk River which flows into Koocanusa Reservoir.

Koocanusa Reservoir was created when the Libby Dam (Montana) was constructed in 1972 to provide flood protection, hydroelectric power, and recreation benefits (Storm et al. 1982). The reservoir is operated by the United States Army Corps of Engineers (USACE) and reached full pool in June 1974 (Storm et al. 1982). At full pool, the reservoir is 155 km in length and straddles the border between Canada (about 68 km in length) and United States (87 km in length; Hamilton et al. 1990). The reservoir (at full pool) has a volume of 7.2 km^3, average surface area of 188 km^2, mean depth of 38 m, and maximum depth of 107 m (which occurs in Montana; the maximum depth at the border is about 46 m). Drawdown to minimum operational pool reduces the total length of the reservoir to 68 km, the volume to 1.1 km^3, and surface area to 59 km^2 (Woods and Falter 1982). At maximum drawdown, this equates to a reduction in reservoir volume of up to 85%, mean depth by 51%, surface area by 69% and total length by 53%, with the largest relative changes occurring in the Canadian portion of the reservoir (Hamilton et al. 1990). Three Canadian rivers, the Kootenay (62% of mean annual inflow), Elk (26%), and Bull (11%), supply most of the reservoir's inflow and, therefore, exert a major influence on the limnology of Koocanusa Reservoir (Woods 1982; Hamilton et al. 1990). Water levels within Koocanusa Reservoir are generally lowest in February through April and highest in summer/early fall (Figure 1.2). Normal annual pool fluctuation is about 35 m and mean residence time is 0.55 years (range 0.14 to 0.73 years) (Storm et al. 1982; Woods and Falter 1982; Hamilton et al. 1990). Since 2008, the USACE have adopted a variable flood control procedure, which improved the chance of refill and provided more normative flow, by drawing the reservoir down less in the winter and releasing more water out in the spring (USACE 2016).

The Ktunaxa First Nation has occupied lands adjacent to, and including, the Kootenay and Columbia Rivers and the Arrow Lakes of BC for more than 10,000 years (KNC 2005). Rivers and streams of the region provide culturally important sources of fish and plants. The Ktunaxa Territory is divided into traditional land districts historically associated with key actors in the Ktunaxa creation story, but also with specific key resources and with specific Ktunaxa individuals or lineages that held particular authority and responsibility for stewardship of resources in those areas (Robertson 2010).

Based on concerns about rising mine-related concentrations of selenium and other constituents of interest within the Elk River basin, Teck initiated monitoring of chemical and biological conditions in the Koocanusa Reservoir in 2013[1]. In the same year (April 2013), the British Columbia (BC) Minister of Environment (MOE) issued a Ministerial Order (Number M113) requiring Teck to develop a plan for the Designated Area[2] to achieve the following outcomes:

- protection of aquatic ecosystem health;

[1] For purposes of this study, Koocanusa Reservoir refers to lands and waters wholly contained within Canada. The first study in the reservoir undertaken by Teck was an evaluation of sediment quality (Minnow 2014a) and water quality.

[2] The Designated Area as defined by Ministerial Order M113 and Permit 107517 is: "a portion of southeastern British Columbia that contains the Elk Valley Watershed and the portion of Lake Koocanusa within Canada. References to the Elk Valley are references to the Designated Area."

- management of bioaccumulation of contaminants in the receiving environment (including fish tissue);
- protection of human health; and
- protection of groundwater.

In response, Teck developed the Elk Valley Water Quality Plan (EVWQP), with input from the public, First Nations, governments, technical experts, and other stakeholders, to guide efforts to ensure the health of the watershed, while allowing for mining to continue (Teck 2014). The EVWQP was approved by the BC Minister of Environment on November 18, 2014.

Discharges from Teck's coal mines to the Elk River watershed are authorized by the BC Ministry of Environment (MOE) through permits that are issued under provisions of the *Environmental Management Act.* Permit 107517, which specifies the terms and conditions associated with those discharges, was issued November 19, 2015 following completion of the EVWQP, and was recently amended on June 5, 2017. The relevant permit requirement for this report is:

> (Section 10.8) ***"****The Permittee must prepare on an annual basis a report summarizing activities and monitoring results. The report must be submitted to the Lake Koocanusa Monitoring and Research Working Group (Lake Koocanusa Working Group)*[3] *and the EMC by June 30 of each year."*

A three-year monitoring program was initiated in 2014 to characterize and compare chemical and biological conditions in the reservoir downstream from the Elk River compared to upstream. Results of monitoring completed in 2014 and 2015 were reported by Minnow (2015b, 2016a). This report presents the 2016 monitoring results in accordance with the annual reporting requirement as per Section 10.8 of the permit, along with the combined results of all three years of study completed (2014 to 2016), a summary of water monitoring results, results from the burbot study (Minnow 2015a), and results from the initial sediment quality study completed in 2013 (Minnow 2014a, mentioned in footnote #2, above).

1.2 Objectives

The overall objective of the Koocanusa Reservoir (Canadian portion) monitoring program conducted in 2014 to 2016 was to assess conditions in the reservoir near and downstream from

[3] The Permit specifies that the Working Group will be established under the BC & Montana government to government Memorandum of Understanding. The Permittee (Teck) is required to participate fully in the Koocanusa Reservoir Monitoring and Research Working Group.

the Elk River compared to upstream, to identify differences that may be attributable to influences from the Elk River. The types of data that were collected included:

- Water, sediment, and tissues of zooplankton, benthic invertebrates, and fish for chemical analysis;
- Phytoplankton, zooplankton, and benthic invertebrates for analysis of community structure;
- Fish measurements related to survival, growth, reproduction, and energy storage as indicators of fish health and population status; and
- Chlorophyll-a in water and seston biomass for analysis of productivity.

Measurement endpoints specific to each sample type were statistically evaluated to identify differences downstream compared to upstream from the Elk River, and for endpoints that differed among areas to determine if they were consistent among years or suggested an increasing or decreasing pattern.

The fluctuations of water levels within the reservoir (Figure 1.2) result in large seasonal and annual variation in water volume (Photo 1.1) and flow characteristics, as well as annual dewatering of large littoral (shallow shoreline) areas. These hydraulic factors are anticipated to influence chemical and biological characteristics within the reservoir and must be considered in the evaluation of potential influences from the Elk River.

1.3 Linkage to the Adaptive Management Plan

As required in Permit 107517 Section 11, Teck has developed an Adaptive Management Plan (AMP; Teck 2016a) to support implementation of the EVWQP, to achieve water quality and calcite targets, ensure that human health and the environment are protected, and where necessary, restored, and to facilitate continual improvement of water quality management in the Elk Valley. The AMP was submitted to the Environmental Monitoring Committee (EMC)[4] and MOE Director July 31, 2016 as required by the Permit. Study designs for many programs were established before the AMP was submitted. The AMP is currently under review, and Teck is working to incorporate input received from the EMC. Teck will work to embed elements of the AMP within each program through reviews of monitoring programs at the study design and

[4] EMC refers to the Environmental Monitoring Committee, which Teck was required to form as a requirement of Permit 107517. The EMC consists of representatives from the MOE, the Ministry of Energy and Mines, Environment Canada, the Ktunaxa Nation, Interior Health Authority, and the Permittee. The EMC reviews submissions and provides technical advice to Teck and the MOE Director regarding monitoring programs.

Photo 1.1: Photos Showing Sunshine Houseboats & Marina Docks within Gold Bay of Koocanusa Reservoir, in April of 2014, 2015, and 2016

report stages through implementation of the AMP. Data from the aquatic monitoring programs will feed into the adaptive management process to specifically address Big Questions #5 (Does monitoring for mine-related effects indicate that the aquatic ecosystem is healthy?) and #2 (Will aquatic ecosystem health be protected by meeting the long-term site performance objectives?). Following an adaptive management framework, evaluation of data collected in the Canadian portion of Koocanusa Reservoir will be used to inform adjustments to the future monitoring design within the reservoir.

2 METHODS

2.1 Overview

Annual study designs for the sampling conducted in the Canadian portion of the Koocanusa Reservoir in 2014 to 2016 were reviewed by the EMC and advice from the EMC was considered in updates to the study designs prior to implementation of field sampling (Minnow 2014b, Minnow 2015c, Minnow 2016b). Data analysis and presentation of results also reflects input provided by the EMC.

Two areas were sampled for sediment, plankton, and benthic invertebrates in Koocanusa Reservoir (upstream and downstream from the Elk River; Figure 2.1). The downstream area was maintained in the same location for all study years (i.e., Area T4), whereas the upstream area (Area T2) was moved 3.5 kilometres (km) further upstream in 2015 (relative to 2014). The area was moved as a result of the EMC's recommendation to relocate Teck's upstream water sampling station (RG_KERRRD, previously RG_USELK), to ensure that it was sufficiently distant from any potential influence of the Elk River (Figure 2.1). The new area was referred to as TN. Areas in the vicinity of the mouths of Sand Creek, Elk River, and Gold Creek were sampled for fish in all three years (Figure 2.2).

In February 2014 and 2015 (sampling was not conducted in February 2016), the following samples/measures were collected at the fish sampling areas identified on Figure 2.2 (with the exception of near the mouth of Gold Creek in 2015, where thin ice conditions presented a safety hazard) (Table 2.1):

- *In situ* water quality profiles (one per fishing area); and
- Fish tissue samples (target included 10 female burbot [*Lota lota*] and rainbow trout [*Oncorhynchus mykiss*], others such as bull trout [*Salvelinus confluentus*] were sampled opportunistically).

In April of 2014, 2015 and 2016, the following samples/measures were collected from the areas identified on Figures 2.1 and 2.2 (Table 2.1):

- *In situ* water quality profiles (one in the middle of each benthic invertebrate tissue sampling area [T2/TN and T4], and one in each fish sampling area);
- Benthic invertebrate tissue samples (one composite sample at each of the areas upstream and downstream from the Elk River [T2/TN and T4]);
- Fish tissue samples (up to 10 each of the following species: burbot, largescale sucker [*Catostomus macrocheilus*], peamouth chub [*Mylocheilus caurinus*], northern

[a] Sand Creek fishing area is upstream of the Elk River confluence, while the Elk River and Gold Creek fishing areas are downstream of the Elk River.

[b] T2/TN were located upstream of the Elk River confluence, while T4 was downstream of the Elk River. The upstream location, T2, was relocated further upstream from the mouth of the Elk River for the August 2015 and subsequent field programs.

[c] Gold Creek area was not sampled in February 2015 where thin ice conditions presented a safety hazard.

[d] Species sampled included one or more of the following: bull trout, burbot, kokanee, largescale sucker, mountain whitefish, northern pikeminnow, peamouth chub, rainbow trout, redside shiner, westslope cutthroat trout, yellow perch.

pikeminnow [*Ptychocheilus oregonensis*], redside shiner [*Richardsonius balteatus*], yellow perch [*Perca flavescens*], bull trout, rainbow trout, westslope cutthroat trout [*O. clarki lewisi*], and mountain whitefish [*Prosopium williamsoni*]; and

- Peamouth chub (2014, 2015 and 2016), northern pikeminnow, yellow perch, largescale sucker, and redside shiner (2015 and 2016) for the fish health assessment (e.g., 20 males and 20 females per fish sampling area).

In August of 2014, 2015, and 2016, the following samples/measures were collected from the areas identified on Figure 2.1 (Table 2.1):

- *In situ* water quality profiles (one at each benthic invertebrate/plankton sampling station [n = 5 per area], and one at each fish sampling area);
- Sediment chemistry, phytoplankton community, zooplankton community, zooplankton tissue, benthic invertebrate community, chlorophyll-a, and seston biomass (five samples each, at each upstream and downstream area);
- Benthic invertebrate tissue samples (one composite sample from each of the areas upstream and downstream from the Elk River); and
- Fish tissue samples (target species included up to 10 rainbow trout [in 2014], 10 northern pikeminnow [in 2015 and 2016], 10 kokanee [*O. nerka*; 2014, 2015 and 2016], and any sport fish collected opportunistically in 2016).

An assessment of the quality of analytical data collected during the three-year sampling program is provided in Appendix A. Details related to sampling activities described above are provided in the sections that follow.

2.2 Water Quality

2.2.1 *In Situ* Water Quality

In association with biological sampling for the current study, *in situ* measurements of water quality were completed in February, April, and/or August, 2014 to 2016. *In situ* water temperature, dissolved oxygen (DO), pH, and specific conductance (i.e., temperature-standardized measurement of conductivity) were measured as vertical profiles at one meter intervals starting just below the water surface. The *in situ* water quality measurements were taken using a calibrated YSI 556 MDS (Multiparameter Display System) meter equipped with a YSI 6820 Sonde (YSI Inc., Yellow Springs, OH), or similar portable multi-parameter unit. Additional water quality information collected to support the interpretation of biological data included Secchi depth, and observations of water colour and clarity (Appendix B).

2.2.2 Routine Water Quality

Routine water quality monitoring was conducted in accordance with Teck's Regional Water Monitoring Plan (Teck 2016b, 2017). Permit 107517 requires the collection of water samples at five stations that are located within the Canadian portion of the reservoir (Figure 2.1). Four of the stations are referred to as receiving water sampling sites (RG_KERRRD, RG_DSELK, RG_GRASMERE, RG_USGOLD), while the fifth station (RG_DSELK) is an Order station, mandated by the MOE, for which site performance objectives (SPOs) have been established. The SPOs for RG_DSELK are 2 µg/L for total selenium (equivalent to the BC water quality guideline), 3 mg/L for nitrate-nitrogen (equivalent to the BC water quality guideline; hereafter referred to as nitrate), 308 mg/L for sulphate (consistent with the BC water quality guideline of 309 mg/L for moderately soft/hard to hard waters [i.e., 76 – 180 mg/L hardness]), and hardness based for dissolved cadmium[5] (functionally equivalent to the long-term BC water quality guideline).

In addition to the five water quality monitoring locations described above, water quality was also assessed on the lower Kootenay River at Wardner Bridge (RG_ WARDB), and the lower Elk River (RG_ELKMOUTH). Flow data from Environment Canada's (2017) closest hydrometric stations (i.e., Kootenay River in Fort Steele [station no. 08NG065] and Elk River in Fernie [station no. 08NK002]) on each river were also downloaded to determine an approximate ratio of flow from the Elk River compared to the Kootenay River into Koocanusa Reservoir. The respective watershed areas between the location where the hydrometric station was situated and Teck's river monitoring stations were also considered when determining the approximate ratio of flow from the Elk River compared to the Kootenay River.

The surface water monitoring program for Koocanusa Reservoir (Canadian portion) and the two river monitoring stations included the collection and/or analysis of multiple parameters on a monthly basis, except from April 1st to July 15th, when samples were collected weekly. Initially at the water quality stations on Koocanusa Reservoir, a profile of the water was conducted and if there was a thermocline (change of 1°C over 1 m change in depth), the water column was considered stratified. If stratified, a composite sample formed from three evenly spaced grab samples was collected throughout the epilimnion, and another composite from the hypolimnion. If the water was not stratified, a sample was collected at 3 m from the surface, 3 m from the substrate, and at the mid-point of the water column. Field parameters for the reservoir and river stations included water temperature, DO, specific conductance, pH, and Secchi depth (in

[5] Dissolved cadmium SPO is hardness dependent based on the following formula:

Dissolved cadmium (in µg/L) = $10^{0.83\log10(\text{hardness})-2.53}$ where hardness is in mg/L of $CaCO_3$

reservoir only). Conventional parameters included specific conductance, total dissolved solids (TDS), total suspended solids (TSS), hardness, alkalinity, dissolved organic carbon (DOC), total organic carbon (TOC), and turbidity. Major ions included bromide, fluoride, calcium, chloride, magnesium, potassium, sodium, and sulphate. Nutrients included ammonia, nitrate, nitrite, total Kjeldahl nitrogen (TKN), orthophosphate, and total phosphorous. Total and dissolved metals analysis included aluminum, antimony, arsenic, barium, beryllium, bismuth, boron, cadmium, chromium, cobalt, copper, iron, lead, lithium, manganese, mercury, molybdenum, nickel, selenium, silver, strontium, thallium, tin, titanium, uranium, vanadium, and zinc (Teck 2016b, 2017). Chlorophyll-a samples were also collected within the reservoir for laboratory analysis starting in April 2015.

2.2.3 Data Analysis

Vertical water quality profiles that were completed in conjunction with biological sampling were plotted to determine if any stratification or gradients in temperature, DO, pH, and/or conductivity were occurring in any of the sampling areas. Data collected from areas downstream from the Elk River were also compared to data collected upstream.

Statistical analysis of water quality data focused on monthly mean concentrations for the Order constituents (i.e., nitrate, selenium, and sulphate; cadmium was excluded as most samples [90%] were less than the method detection limits [<0.00001 mg/L in 2014 and <0.000005 in 2015 and 2016] at areas both upstream and downstream of the Elk River. Samples were generally collected at the surface, middle, and bottom depths during each sampling event (i.e., as conditions in the reservoir were unstratified). Pairwise statistical comparisons of monthly mean concentrations between depths (surface vs. middle, surface vs. bottom, and middle vs. bottom) were conducted by station (RG_KERRRD, RG_USELK, RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER) using a paired t-test. When the assumption of normality (Shapiro-Wilks' test with significance level [α] = 0.05) was not met, the non-parametric Wilcoxon signed rank test was used. A Bonferroni-adjusted α of 0.1/3 = 0.033 was used for paired t-test and Wilcoxon signed rank tests to control the Type I error rate for the n = 3 pairwise comparisons for each station. Results of these analyses were used to determine whether the depths should be analyzed separately or pooled in the analyses described below.

Statistical comparisons of nitrate, selenium, and sulphate concentrations between downstream stations (i.e., RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER) and upstream stations (RG_USELK in 2014 and RG_KERRRD in 2015 and 2016) were conducted to assess differences among years and between stations. The statistical comparisons were conducted on the differences (downstream of the Elk River – upstream of the Elk River) in monthly mean concentrations to remove the influence of season using a method analogous to a two-way

ANOVA with factors *Area* and *Year*. The differences in monthly mean concentrations between areas were tested using ANOVA (or the Kruskal-Wallis test when assumptions of normality and homogeneity of variances were not met) with factor *Year* (equivalent to testing the *Area*×*Year* interaction in a two-way ANOVA) according to the following hypothesis:

$$H_{01}: \mu_{d\_2014} = \mu_{d\_2015} = \mu_{d\_2016}$$

where μ_{d_2014} represents the mean of the differences in monthly mean concentrations between upstream and downstream stations.

When a difference was detected, pairwise comparisons among years were conducted using Tukey's Honestly Significant Differences method or the Mann-Whitney test ($\alpha = 0.1$). The upstream and downstream station comparisons were conducted by testing whether differences in monthly mean concentrations between stations were different from zero using a one-sample t-test (or Wilcoxon signed rank test when assumptions of normality were not met) by testing the hypothesis:

$$H_{02}: \mu_d = 0$$

The tests for H_{02} were conducted by pooling all years of data when the differences in monthly mean concentrations between stations were not significantly different among years (i.e., H_{01} was not rejected) and were conducted by year when the differences in monthly mean concentrations between stations were significantly different among years (i.e., H_{01} was rejected). An example table showing the results of the analyses is provided in Table 2.2.

The magnitude of difference (MOD) between stations was calculated when a significant difference was detected between stations as:

$$\text{MOD} = \frac{(MCT_{DS} - MCT_{US})}{MCT_{US}} \times 100\%$$

where MCT_{DS} and MCT_{US} are the measure of central tendency for the downstream and upstream stations, respectfully (i.e., mean or median depending on whether the statistical comparison was conducted using a parametric or non-parametric method, respectively). The statistical analyses were conducted using R statistical software (R Core Team 2015).

2.3 Sediment Quality

2.3.1 Sample Collection

Sampling of sediment in the three-year (2014 to 2016) Koocanusa Reservoir monitoring program focused on two transects (i.e., T2/TN and T4). As noted in Section 2.1, the upstream transect (T2) was re-located 3.5 km farther upstream in 2015 (TN) to avoid potential influence

Table 2.2: Description of Two-way ANOVA Statistical Approach Applied to the Evaluation of Spatial and Temporal Differences in Aqueous Parameter Concentrations in Koocanusa Reservoir at Stations Downstream from the Elk River Relative to Upstream Station(s) Using Data Collected in 2014 to 2016

Mean concentrations are reported by station and year. The mean reported here represents the mean of monthly mean concentrations by station.

The test here is for whether the relative difference between downstream of Elk River and upstream of Elk River is the same in each year (i.e., are the lengths of the arrows between station means the same in each year in the figure below?). If there is a significant difference among years, then pairwise comparisons are conducted between years to determine which year(s) is(are) different (Tukey's Honestly Significant Differences or Mann-Whitney tests; α=0.1).

The test here is whether there is a difference downstream of Elk River compared to upstream of Elk River. The hypothesis is tested by comparing the mean relative difference between downstream of Elk River and upstream of Elk River to zero (i.e. are the two stations significantly different from each other?). When the relative difference between stations is similar among years (overall p-value from H_{01}>0.1) then the downstream of Elk River vs upstream of Elk River comparison is conducted by pooling data from all years (and not separated by year).

Parameter	Mean Concentration (mass/volume)						H_{01}: Is the difference between the downstream concentration and upstream concentration equal in all years? Test for Relative Difference Between Areas (Downstream of Elk River - Upstream of Elk River) Among Years					H_{02}: Is the downstream concentration equal to the upstream concentration? = p-value < 0.1

from the Elk River (Figure 2.1). Sediment samples were collected in August in each of the three years from five stations along each transect (Figure 2.1).

Sediment samples for physical and chemical characterization were collected using a stainless steel Petite Ponar (0.023 m^2 sampling area). At each transect (T2 and T4 in 2014, TN and T4 in 2015 and 2016; Figure 2.1), three grabs were collected at each of the five stations to create a composite sediment sample consisting of the top three centimetres (cm) of sediment [i.e., the sediment fraction in which most benthic fauna generally reside (Kirchner 1975)]. Following retrieval of each sediment grab, the ponar was gently opened and lifted to release the collected sediment into a clean plastic tub. If the grab was not complete to each edge of the ponar, or lacked an intact sediment-water surface layer, it was discarded and a new grab was collected. If the grab was acceptable, the top 3 cm were removed and placed into a separate plastic tub. The procedure was repeated until three acceptable grabs were obtained, after which the sample was homogenized using a stainless steel spoon. The homogenized sediment was then transferred to a glass jar [for analysis of polycyclic aromatic hydrocarbons (PAHs)] and a large labelled Ziploc® bag (for all other analyses described in the paragraph below). Sediments were not collected for PAH analysis in 2014 (i.e., only in 2015 and 2016). Samples were subsequently placed in a cooler with ice and transferred to a refrigerator later in the day.

At each sediment sampling station, supporting information was recorded on field sheets, including average Ponar fullness, station depth (m), the presence of algae or macrophytes in samples, sediment texture, and Universal Transverse Mercator (UTM) coordinates (Appendix C).

2.3.2 Laboratory Analysis

Sediment samples (whole sample not sieved) were sent to ALS Environmental in Calgary, Alberta for analysis of PAHs, moisture content, particle size, TOC, and metals/metalloids (hereafter collectively referred to as metals) in the <1 mm fraction (sieved in the lab). For the metals analysis, the <1 mm fraction was representative of whole sediments because samples were collected from depositional areas dominated by fine-grained sediments (i.e., results of particle size analysis indicated that grain size of whole sediment was <1 mm at all sampling locations during the 2014 to 2016 study). This approach is also consistent with previous sampling methodology. Screening at <1 mm ensured that the small sub-sample analyzed by the laboratory did not contain any large grains of sand or gravel that would not be considered representative of the sample as a whole and could bias chemical concentrations expressed relative to sample mass. Sediment sampling quality assurance/quality control (QA/QC) included the collection and analysis of one field duplicate split sample in each sampling event, as well as

assessment of laboratory duplicates, method blanks, and recovery of certified reference materials.

2.3.3 Data Analysis

Sediment particle size distribution and TOC were plotted to aid in the interpretation of the sediment chemistry results. Sediment chemistry data were compared to applicable BC Working Sediment Quality Guidelines (WSQGs) and parameters that exceeded the lowest effect level WSQG (and selenium) were plotted. The lower sediment quality guidelines (i.e., lowest effect level/threshold effect level – LEL/TEL) represent concentrations below which adverse biological effects would not be expected to occur (BCMOE 2017b). In contrast, the highest sediment quality guidelines (i.e., probable effect level/severe effect level – PEL/SEL) represent concentrations above which effects may be observed (BCMOE 2017b).

A two-way ANOVA with factors *Area* and *Year* were used to compare areas located downstream versus upstream of the Elk River over three study years (2014 to 2016; Table 2.3). When the interaction between *Area* and *Year* was significant ($\alpha = 0.1$), the conclusion was that there was a difference between areas, but the difference depended on the year. Comparisons were then conducted between areas separately by year using the contrasts package (Kuhn et al. 2016) in R (R Core Team 2015). When the interaction between *Area* and *Year* was not significant, the significance of the *Area* term in the two-way ANOVA model was assessed and the conclusion was that the differences between areas were similar in each year. An example results table for the two-way ANOVA is provided in Table 2.3. Assumptions of normality and homogeneity of variances were tested on the residuals of the two-way ANOVA using the Shapiro-Wilks' and Levene's tests, respectfully. Data were $\log_{10}$-transformed as required to meet assumptions. When the assumptions could not be met, a rank transformation was used. A more liberal α of 0.01 was used for testing the assumptions, to limit the use of the rank transformation to those instances where assumptions were violated.

At the request of the EMC, the magnitude of difference was calculated in two ways. First, a magnitude of difference was reported for the comparisons between areas (either pooled across years or separately by year) as a standardized difference in terms of the number of within-area/year standard deviations as:

$$\text{MOD} = \frac{(\bar{X}_{DS} - \bar{X}_{US})}{S_r}$$

where $\bar{X}_{DS}$ is the mean for the downstream area, $\bar{X}_{US}$ is the mean for the upstream area, and S_r is the pooled standard deviation of the residuals (i.e., the within-area/year standard deviation) of the two-way ANOVA model.

Table 2.3: Example of Two-way ANOVA Statistical Approach with Factors Area and Year used for Comparisons between Koocanusa Reservoir Areas Located Downstream versus Upstream of the Elk River from 2014 to 2016

Data transformation to meet assumption of normality (S-W test α=0.01) and homogeneity of variance (Levene's test α=0.01). If assumptions could not be met using a log [or log(x+1) when zeros were present] transformation, then the ANOVA was conducted on ranked data. A 0.1 instead of 0.5 significance level was used for testing assumptions to limit the use of the rank transformation to extreme deviation of normality or heterogeneity of variances.

The measure of central tendency was reported to support the statistical comparison. The mean is reported for no transformation, the back-transformed mean on the log scale (i.e. geometric mean) when a log transformation was used, and the median when the rank transformation was used.

P-values for the two-way ANOVA. When there was an interaction between Area and Year, it was interpreted as a difference between areas, but the difference depended on which years were compared. When there was an interaction, the Area and Year p-values were not shown and contrasts were conducted to compare the areas separately by year.

ANOVA contrasts (p-values) were conducted only when there was an interaction between Area and Year.

The magnitude of difference (MOD) was calculated as (downstream of Elk River-Upstream of Elk River)/Upstream of Elk River*100 and was reported when the difference was significant. The MOD was reported by year when there was an interaction between Area and Year, and reported for all years when there was no interaction between Area and Year.

The MOD was also reported in terms of the number of standard deviations (this is the pooled standard deviation from the ANOVA table).

Endpoint	Trans-formation	Measure of Central Tendency (Mean, Geometric Mean, or Median)[a]						Model P-values			P-values for Contrasts Area×Year			Significant Differences and Magnitudes of Difference (%)			Significant Differences and Magnitudes of Difference (number of SD)		
		2014		2015		2016		Area×Year	Area	Year	Downstream of Elk River (T4) vs Upstream of Elk River (T2/TN)			Downstream of Elk River (T4) vs Upstream of Elk River (T2/TN)			Downstream of Elk River (T4) vs Upstream of Elk River (T2/TN)		
		T4	T2	T4	TN	T4	TN				2014	2015	2016	2014	2015	2016	2014	2015	2016
Endpoint A	none	2,631	3,224	3,533	984	3,295	2,547	0.170	0.184	0.641	-	-	-	-			-		
Endpoint B	log	1,394	947	1,194	418	1,449	1,034	0.633	0.092	0.360	-	-	-	* (81%)			* (0.64 SD)		
Endpoint C	log(X+1)	0.51	4.7	0.42	1.6	0.33	0.29	0.086	-	-	0.004	0.161	0.955	* (-89%)	-	-	* (-3.4 SD)	-	-

p-value < 0.1

* indicates a significant difference between the two areas at an α of 0.1.

[a] The measure of central tendency reported is based on the applied data-transformation, as follows: mean for no transformation; geometric mean for $\log_{10}$-transformation; and, median for rank-transformation.

Second, a magnitude of difference was also reported for the comparisons between areas (either pooled across years or separately by year) as a percentage difference in the measure of central tendency between areas relative to the upstream area as:

$$\text{MOD} = \frac{(MCT_{DS} - MCT_{US})}{MCT_{US}} \times 100\%$$

where MCT_{DS} and MCT_{US} are the measures of central tendency for the downstream and upstream areas. The measures of central tendency were reported in the original data units as:

- means when no transformation was used;
- geometric means when a $\log_{10}$-transfomation was used; and
- medians when a rank transformation was used.

The two-way ANOVA with a rank transformation actually compares mean ranks (and not medians). A percent difference between two mean ranks does not provide an estimate of the magnitude of difference between two areas. A percent difference between two medians does provide an estimate of the magnitude of difference; however it is possible to detect a significant difference between mean ranks when the area medians are equal.

2.4 Plankton

2.4.1 Productivity

2.4.1.1 Sample Collection

Productivity was measured based on data collected during Teck's routine water quality monitoring (i.e., for nitrate, phosphorus, orthophosphate, chlorophyll-a, and Secchi depth, as described in Section 2.2.2) and data collected during biological sampling (described below).

Chlorophyll-a samples associated with biological monitoring were collected as depth-integrated samples through the top 10 m of the water column at each of five stations upstream and downstream from the Elk River (i.e., transects T2/TN and T4; Figure 2.1) in August of each sample year. Depth-integrated water samples were collected by lowering a 1 cm inside-diameter plastic tube, equipped with a weight, to a depth of 10 m and, after crimping the tube to ensure no water loss upon retrieval, the tube was pulled to the surface and the water inside the tube was emptied directly into a clean pail. A total of three grabs were composited to form the sample, which was then mixed and split for analysis of chlorophyll-a and phytoplankton community (see Section 2.4.2.1, below). Composite water samples were filtered in the field through a 0.45 µm sterile cellulose acetate membrane filter assisted by a vacuum pump. Following filtration of one litre of water, the membrane filter was removed from the filter

apparatus, folded within a piece of aluminum foil, and placed into a pre-labelled polyethylene (Whirl-Pak™) bag. Samples were stored frozen until shipped to ALS Environmental for analysis.

Chlorophyll-a was also measured *in situ* in 2015 to investigate variability in concentrations at 1 m depth intervals and to test the accuracy of the method by comparing average *in situ* concentrations over the top 10 m to those reported by the laboratory for the 10-m depth-integrated samples. The 2015 *in situ* chlorophyll-a concentrations were measured using a YSI multi-parameter field meter. The meter was fitted with a total algae sensor, which provides separate measurements for both chlorophyll-a and blue-green algae. Measurements were conducted at one meter intervals starting just below the water surface. Collection of chlorophyll-a data using the traditional field filtering and laboratory analysis methods showed that *in situ* measurements underestimated chlorophyll-a concentrations; therefore, *in situ* chlorophyll-a measurements were not collected in 2016.

Seston biomass samples were also collected as a measure of productivity during biological sampling. Samples were collected at the same time and from the same locations as the field filtered chlorophyll-a samples described above. Samples were collected by hauling a 60 µm plankton net through the top 10 m of the water column at each station five times. Samples were transferred to plastic collection jars and preserved with 5% formalin solution. Samples were later filtered and residual material dried and weighed as described by Wetzel and Likens (2000) to provide an estimate of total seston productivity (i.e., total seston weight per unit volume of water).

2.4.2 Community Composition

2.4.2.1 Sample Collection

Samples for analysis of phytoplankton community structure were collected as depth-integrated samples through the top 10 m of the water column from five stations in each transect (T2 and T4 in 2014, TN and T4 in 2015 and 2016; Figure 2.1), as described in Section 2.4.1.1. Immediately following collection of the 100 mL sample, Lugol's solution was added to the sample for preservation (enough volume to darken the solution to a weak tea colour). The sample was mixed with the Lugol's solution by gently tipping the jar twice. Samples were maintained at room temperature until shipment to the laboratory (Plankton R Us, Winnipeg, Manitoba).

Samples for analysis of zooplankton community composition were collected using a 19 cm diameter, fine mesh (i.e., 60 µm) plankton net, vertically hauled through the top 10 m of the water column at each sampling station, based on methods described by BCMWLAP (2003). A

total of three vertical hauls were collected and composited to form a single community sample at each of the sampling stations (T2 and T4 in 2014, TN and T4 in 2015 and 2016; Figure 2.1). Each sample was carefully transferred into a pre-labelled plastic sampling jar, and preserved to a level of 10% buffered formalin. Samples were maintained at room temperature until shipment to Plankton R Us. At each plankton sampling station, supporting information was recorded on field sheets, including weather conditions, Secchi depth, and UTM coordinates (Appendix D).

2.4.2.2 Laboratory Analysis

Phytoplankton and zooplankton samples collected for community analysis were sent to Plankton R Us Inc. (Winnipeg, MB) for taxonomic identification.

For phytoplankton samples, 10 mL aliquots of preserved sample were gravity settled for 24 hours. Cell counts were then performed using the Ütermohl technique as modified by Nauwerck (1963), using an inverted microscope at magnifications of 125X, 400X, and 1200X with phase contrast illumination. Specimens were identified to the lowest taxonomic level possible. Cell counts were converted to wet weight biomass by approximating cell volume. Estimates of cell volume for each species were obtained by measuring up to 50 cells of an individual species and applying the geometric formula best fitted to the shape of the cell (Vollenweider 1968; Rott 1981). A specific gravity of 1 was assumed for cellular mass.

Zooplankton samples were brought to a standard volume by settling the sample for 24 hours and then decanting the upper liquid. The decanted liquid was microscopically viewed to ensure no animals were lost. For cladocerans and copepods, sub-sampling was performed (using an automatic pipette) on samples that contained large numbers of specimens. All samples were sub-sampled (using an automatic pipette) for rotifer enumeration. One millilitre sub-samples (to a maximum of ¼ of the sample) were allowed to settle in a Sedgwick-Rafter counting chamber. Rotifers were enumerated by counting the entire counting chamber (9.6 cm^2). All enumerations and identifications were conducted using a Zeiss compound research microscope equipped with a phase-contrast condenser at magnifications ranging from 98X to 250X. Specimens were identified to the lowest taxonomic level possible. Once numbers of organisms within each sample were established, these values were converted to densities per litre. This was accomplished by dividing the number of organisms per volume of sample by the total volume of lake water filtered in the field (i.e., net mouth area × depth of haul × number of hauls).

The biomass of major taxonomic groups within each zooplankton sample was also determined. To calculate biomass, literature values from published length-weight regression equations were applied (list of references provided at the end of Appendix D). Biomass for each taxonomic group was calculated by multiplying the number enumerated for that sample by the mean individual weight.

For both phytoplankton and zooplankton community samples, sub-sampling accuracy was assessed by performing replicate counts on 10% of samples (in this case, one sample each year). Replicate samples were chosen at random and processed at different times from the original sample to reduce bias.

2.4.3 Tissue Chemistry

Zooplankton were collected for analysis of tissue chemistry using an 80 µm mesh net (30 cm diameter) vertically hauled through the top 10 m of the water column. A slightly larger mesh size was used for tissue collection to ensure the sample mostly consisted of zooplankton (and was not confounded by the presence of phytoplankton). A total of 10 vertical hauls were collected at each station, composited and filtered through the net a second time (to remove as much water as possible) to ensure sufficient sample weight for analysis. Samples were then transferred to sterile cryovials and frozen, pending shipment to the University of Missouri Research Reactor Center (MURR) for freeze-drying and analysis of metals (including mercury) using high-resolution Inductively Coupled Plasma Mass Spectrometry (ICP-MS).

2.4.4 Data Analysis

Based on input from the EMC, further understanding of the trophic status of the lake was requested so a literature search was conducted to find criteria for determining the trophic status in lakes and reservoirs. Representative criteria were chosen based on their relevance, as well as to give a representation of jurisdictional differences in criteria. Criteria were then grouped together by variable (total phosphorus, chlorophyll-a, Secchi depth and total nitrogen) into six trophic classifications, where possible (Table 2.4). These classifications are Ultra-oligotrophic, Oligotrophic, Mesotrophic, Meso-Eutrophic, Eutrophic and Hyper-Eutrophic. The trophic classification used in British Columbia (Nordin 1985) was selected for screening against monthly averages for total phosphorus, chlorophyll-a, and Secchi depth from the reservoir station upstream of the Elk River (RG_KERRRD) and the four stations downstream of the Elk River (RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER).

Phytoplankton and zooplankton communities were evaluated between areas and over time using primary metrics of mean taxonomic richness [as identified to lowest practical level (LPL)], mean organism density (average number of cells or organisms per litre), and mean biomass (mass of cells or organisms per litre). Comparisons were made based on absolute and relative density as well as absolute and relative biomass. Relative density and relative biomass were calculated as the density or biomass of each respective taxa and group relative to the total number of cells or organisms in the sample for dominant taxa and groups. Dominant taxa were defined as taxa representing at least 5% of the total cell or organism density at one or more

stations. For zooplankton, males and females belonging to the same taxa were combined for analysis. Zooplankton eggs were omitted from analyses (viability was not determined). All community endpoints were summarized by reporting the minimum, maximum, mean, median, standard deviation (SD), and sample size for each sampling area and year. Statistical comparisons were based on differences in major taxonomic groups. A two-way ANOVA was used to assess spatial and temporal differences in plankton community endpoints in the area downstream from the Elk River (T4) compared to the upstream area (T2/TN) in 2014 to 2016, as described in Section 2.3.3.

Non-metric multi-dimensional scaling (NMDS) was used to separately reduce the phytoplankton and zooplankton taxonomic data matrices to fewer dimensions. NMDS is a method to visualize the level of similarity of samples based on the rank of the similarities (Clarke 1993). The NMDS takes the N-dimensional (here N = number of taxa) coordinates of each sample (i.e., station in a given area/year) and defines a set of new n-dimensional coordinates that reflect the locations (rank distances) among samples. The n = 2 dimension is frequently used because the sample stations can be plotted on a 2-dimensional scatterplot.

The Bray-Curtis distance was used as the measure of relative community similarity or dissimilarity using PC-ORD© (McCune and Mefford 2011). Taxa occurring in two or fewer of the 30 samples were removed from the dataset as their exclusion from multivariate analyses reduces 'noise' (Bailey et al. 2004). The 'slow and through' option, which uses the following settings, was applied: maximum iterations = 400, instability criterion = 0.00001, number of real runs = 40, and number of randomized runs = 50 (McCune and Grace 2002). All NMDS ordinations were evaluated for solution stability, final stress <0.2, and Monte Carlo randomized determination of interpretable axes of $p < 0.05$ (McCune and Grace 2002).

NMDS of non-transformed data often results in "shallow interpretation in which only the pattern of a few, very common species is represented" (Clarke 1993). Thus, a suite of transformations was applied (log_{10}, square root, 4th root, power 2, and power 4) which assigned different weights to the rarer taxa, relative to abundant taxa (Clarke 1993). All transformations were evaluated because it was not known *a priori* which transformation would best explain the differences in community structure (i.e., the appropriate weight to assign to rare taxa relative to abundant taxa). Results were reported for the transformation that had mean skew and kurtosis values closest to zero. The NMDS analyses were conducted using absolute abundance taxa data matrices at LPL. The 2- or 3-dimensional ordination was selected based on PC-ORD© decision criteria (final stress less than 0.2, randomization test with $p < 0.05$, and a reduction of at least 5 points of stress with each additional axis). The NMDS Axis 1 scores were used to

describe the community matrix because it explained most of the variability in the community matrix.

Selenium concentrations in zooplankton were plotted and compared statistically between the downstream area (T4) and the upstream area (T2/TN) from 2014 to 2016 using a two-way ANOVA as described in Section 2.3.3. Data were compared to the interim BC guideline for benthic invertebrate tissue (4 µg/g dw), EVWQP Level 1 benchmarks for effects to benthic invertebrates (13 µg/g dw), and dietary effects to juvenile fish (11 µg/g dw).

2.5 Benthic Invertebrates

2.5.1 Community

2.5.1.1 Sample Collection

Benthic invertebrate community sampling was completed at each of five stations upstream and downstream from the Elk River (i.e., transects T2/TN and T4; Figure 2.1) in August of each sampling year (2014 to 2016), when water levels are most stable and benthic invertebrate communities are at peak biomass and diversity (BCMOE 2006). Benthic invertebrate community samples were collected using a stainless steel petite-Ponar sampler. A single sample, consisting of a composite of five petite-Ponar grabs (i.e., 0.116 m^2 total sampling area) was collected at each station. Care was taken to ensure that each grab captured the surface material and was full to each edge of the ponar sampler, with any incomplete grabs discarded. Each acceptable grab was field-sieved using 500 µm mesh, with the retained material carefully transferred to a plastic jar containing both external and internal station identification labels. Samples were preserved to a level of 10% buffered formalin in ambient water. At each benthic invertebrate sampling station, supporting information was recorded, including substrate description, sampler fullness, sampling depth, Secchi depth, and UTM coordinates (Appendix E).

2.5.1.2 Laboratory Analysis

Benthic invertebrate community samples were submitted to ZEAS Inc. (Nobleton, ON) for analysis following standard sorting methods which incorporated recommended Environment Canada QA/QC procedures for assessing sub-sampling error and sorting recovery checks (i.e., Environment Canada 2012). Upon arrival at the laboratory, a biological stain was added to each benthic invertebrate community sample to facilitate sorting accuracy. Samples were washed free of formalin in a 500 µm sieve and the remaining sample material examined under a stereomicroscope at a magnification of at least ten times. Benthic invertebrates were removed from the sample debris and placed into vials containing a 70% ethanol solution according to major taxonomic groups (e.g., phyla, orders). A senior taxonomist enumerated and identified

benthic organisms to LPL (typically to genus or species) using the most current taxonomic keys (Appendix Table E.1). Following identification, representative specimens of each taxa were preserved in a 75% ethanol-3% glycerol solution in separately labelled vials to create a voucher collection.

2.5.2 Tissue Chemistry

2.5.2.1 Sample Collection

Composite benthic invertebrate tissue samples were collected upstream and downstream from the Elk River in both April and August in 2014, 2015, and 2016 (Figure 2.1). A total of 20 petite-Ponar grabs (four from each of the five sampling stations identified on Figure 2.1) were collected to obtain a single sample from each area during each sampling event. Each full grab was placed into a 500 µm mesh sieve bag and sieved free of material less than 500 µm in size. The remaining material was then transferred to a white enamel tray for removal of benthic organisms using tweezers. All visible organisms were removed from the debris/sediment, rinsed clean using ambient water, and placed into a sterile cryovial.

2.5.2.2 Laboratory Analysis

Samples were stored frozen, pending shipment to MURR for determination of moisture content (by freeze drying) and analysis of metals (including mercury) using high-resolution ICP-MS.

2.5.3 Data Analysis

Benthic invertebrate communities were evaluated between areas and over time similar to plankton communities (Section 2.4.4). Primary metrics of mean taxonomic richness (as identified to LPL) and mean organism density (average number of organisms per m^2) were calculated. Absolute and relative density (calculated as the density of each respective taxa and group relative to the total number of organisms in the sample) for dominant taxa and groups were also calculated. Dominant taxa were defined as those species representing at least 5% of the total organism density at one or more stations. Immature Tubificinae (with and without hair chaetae) were combined for analysis. All community endpoints were summarized by reporting the mean, median, minimum, maximum, SD, and sample size for each sampling area and year.

A two-way ANOVA was used to assess spatial and temporal differences in benthic invertebrate community endpoints using methods described in Section 2.3.3. Benthic invertebrate communities were also assessed using NMDS as described in Section 2.4.4.

Selenium concentrations in benthic invertebrates were compared between the downstream areas (T4) and the upstream area (T2/TN) from 2014 to 2016 using a two-way ANOVA as described in Section 2.3.3. Selenium concentrations in benthic invertebrates were also plotted

and compared to the BCMOE interim guideline of 4 µg/g dw and the Level 1 benchmarks (Teck 2014) for the EVWQP (i.e., 13 and 11 µg/g dw for effects on benthic invertebrate reproduction and for dietary effects to fish, respectively).

2.6 Fish

2.6.1 Sample Collection

Fish for the health assessment and evaluation of tissue chemistry were targeted in three study areas in Koocanusa Reservoir – two downstream from the Elk River (Elk River and Gold Creek), and one upstream from the Elk River (Sand Creek) (Figure 2.2). Fish sampling employed a number of standard techniques, including angling, burbot traps, gill nets, hoop nets, minnow traps, and/or seining, which varied according to study year based on provincial fish collection permit conditions.

Angling was used to catch fish in February 2014 and 2015, April 2014, 2015 and 2016, and April 2016. In February 2014, angling was conducted through a hole bored in the ice using a baited (e.g., worms, squid, or salted salmon row) hook. Angling in April (2014 to 2016) and August (2015) was conducted from a boat using a single hook baited with salted salmon roe or worms. In August 2014, when rainbow trout were specifically targeted for tissue sampling, downrigging was conducted from a trolling boat. Downrigging was largely unsuccessful and was discontinued in subsequent monitoring years (i.e., 2015 and 2016).

Burbot traps were used to target burbot in February and April of 2015. Traps were set and retrieved by boat. Bait (i.e., salmon roe) was placed into bait bags in each trap, and the traps were slowly lowered to the bottom of the reservoir, ensuring that there was enough rope to allow the buoy to float at the surface. Burbot traps were left overnight and checked the following day (approximately 24 hour period).

Three foot-diameter hoop nets were used to collect fish in February, April, and August 2014, April and August 2015, and in April 2016. Leads were attached to the opening of each net, and the nets were typically set perpendicular to shore. In strong flow areas, the mouth of the net was directed downstream to minimize clogging from debris. The lead and net were secured with anchors, and floats were attached to the net to mark its location on the water surface. Hoop nets were left to fish overnight (i.e., approximately 24 hours).

Gill nets were used as the main method to capture fish in April and August of 2016. Nets of varying lengths (i.e., 75’ to 150’) and mesh sizes (1”, 1.5”, 2”, 2.5”, 3”, 4”, and 5”) were deployed. Gill nets were typically set for a maximum of 2 hours (often less) to minimize bycatch mortalities.

Minnow traps were used during the April 2015 sampling program to target redside shiner. Traps were baited with cat food, which was placed in a screened (<1 mm mesh) 250 mL container, to ensure that fish did not have access to the food. Minnow traps were set on the reservoir bottom in shallow areas, or suspended at various depths in the water column from docks or woody debris near the shore. After approximately 24 hours, traps were checked and re-set, as necessary.

Seining (using a 15 m by 0.9 m net with a 0.3 cm mesh size) was also used to characterize the small-bodied fish community in each of the study areas in August 2014.

Angling, burbot trapping, hoop netting, gill netting, minnow trapping, and seining locations were marked using a handheld Global Positioning System (GPS) with coordinates recorded in UTMs. The date and time of deployment and the date and time of retrieval, were recorded on field sheets. All fish captured were identified and enumerated, and released at the point of capture or sampled as described below (Appendix F).

2.6.2 Field Processing

Fish retained for the assessment of health endpoints were transported to a dedicated field laboratory for processing as soon as possible following capture (i.e., within hours). If not already dead, fish were sacrificed by a decisive blow to the head. Fork and total lengths were measured to the nearest millimeter using a standard measuring board. Weights were measured using appropriately-sized spring scales (e.g., 50 g, 100 g, 300 g). Each fish was opened and the sex and/or sexual maturity recorded. Whole gonads and livers were removed from each sexually mature fish and weighed to the nearest milligram (0.001 g) using an analytical balance with a surrounding draft shield. Whole ovaries from each sexually mature female were then placed in a labelled polyethylene (Whirl-Pak®) bag. A skinless, boneless muscle fillet sample was collected from each female fish and placed into a separate Whirl-Pak® bag. Following these measures, age structures (i.e., otoliths, dorso-lateral scales, and/or dorsal spines) were removed from all fish. Each age structure was wrapped separately in waxed paper and placed inside a labelled envelope. Whole bodies of male fish (i.e., carcasses and all associated internal organs previously removed for weighing) were placed into a Whirl-Pak® bag. Any internal or external parasites, deformities, erosions (fin and gill), lesions, or tumours observed during processing (i.e., DELT survey; Sanders et al. 1999) were recorded on field sheets.

Fish retained for lethal tissue sampling were similarly transported to a dedicated field laboratory for processing as soon as possible following capture. Each fish was weighed using an analytical balance (0.001 g) or appropriately-sized spring scale (e.g., 50 - 2000 g) and fork and total lengths were measured using a measuring board equipped with a metre stick (± 1 mm). Each fish was then opened and the sex and/or sexual maturity recorded (if obvious). Ovaries

were removed from mature female fish and placed in a labelled Whirl-Pak® bag. A skinless, boneless muscle fillet (minimum of 25 g) was also collected from each fish and placed into a separate Whirl-Pak® bag. Age structures (i.e., otoliths and dorso-lateral scales) were removed from each fish, wrapped separately in waxed paper, and placed inside a labelled envelope. Any internal or external parasites, deformities, erosions (fin and gill), lesions, or tumours observed during processing (i.e., DELT survey; Sanders et al. 1999) were recorded on field sheets.

Fish collected for non-lethal tissue sampling or body measurements were processed in the field. Weights and lengths were measured using spring scales and a measuring board, respectively. External fish condition, including the presence of any parasites, deformities, lesions, or parasites, was documented. A muscle sample was collected from each fish using a biopsy punch (4 mm acu-punch). Following extraction of the biopsy sample, skin was removed from the sample using a scalpel and the remaining muscle placed into a sterile Nalgene cryovial. Samples were kept in a cooler on ice until transfer to a freezer later in the day. The fish was then released near its capture location.

All samples collected (i.e., eggs, ovaries, muscle, age structures, and whole bodies) were stored frozen pending shipment to the respective laboratory for analysis immediately following completion of field sampling.

2.6.3 Laboratory Analysis

Fish tissues collected for age analysis (i.e., otoliths, scales, and/or dorsal spines) were submitted to North Shore Environmental Services in Thunder Bay, Ontario. Otoliths were prepared using a “crack and burn” method which involves cracking the otoliths in half and then lightly burning the otolith to make the annuli visible. Dorsal spines were cleaned, embedded in epoxy resin and, after the epoxy hardened, sectioned using a low-speed isomet diamond saw. Each otolith, dorsal spine, or scale sample was then mounted on a glass slide using a mounting medium and examined under a compound microscope using transmitted light to determine fish age. For each structure, the age and edge condition was recorded along with a confidence rating for the age determination.

Tissue samples for chemical analysis were submitted to MURR. Samples were first freeze-dried for determination of moisture content and then analyzed for metals (including mercury) using high-resolution ICP-MS. Results were reported on a dry weight (dw) basis, along with moisture content (based on the difference between wet and freeze-dried sample weights) to allow conversion to wet-weight values, as required.

2.6.4 Data Analysis

2.6.4.1 Fish Health Assessment

Fish health endpoints representing five response categories including survival (mean age), energy use - growth (weight-at-age and length-at-age), energy use - reproduction (relative gonad weight), and energy storage (condition and relative liver weight) were plotted and evaluated separately for male and female fish (Table 2.5). These endpoints are recognized as indicators of fish health by Environment Canada, and are consistent with those required for fish health monitoring under the national Environmental Effects Monitoring (EEM) program for mines (Environment Canada 2012). Statistical analyses of fish health endpoints were consistent with procedures outlined in the EEM technical guidance document (Environment Canada 2012), but adapted to accommodate multiple years of data using two-way analyses of variance and two-way analyses of covariance (Table 2.6).

Table 2.5: Effect Indicators and Endpoints for the Fish Population Health Study (Environment Canada 2012)

Effect Indicators[a]	Effect Endpoints
Survival	Age
Growth (energy use)	Size-at-age (body weight relative to age)
	Size-at-age (length relative to age)[b]
Reproduction (energy use)	Relative gonad size (gonad weight against body weight)
Energy storage	Condition (body weight against length)
	Relative liver size (liver weight against body weight)

[a] Endpoints to be used for determining "effects" as designated by statistically significant differences between exposed and reference areas (Environment Canada 2012).

[b] This analysis is for informational purposes only, and significant differences between exposed and reference areas are not necessarily used to designate an effect (Environment Canada 2012).

Analyses of the fish health endpoints were conducted separately by sex. Fish with a gonadosomatic index (GSI = gonad weight/body weight × 100%) less than 1% (i.e., non-developed fish) were removed from the analysis of the reproduction endpoint (i.e., relative gonad weight), with one exception. If the majority of fish captured were non-developed, the developed fish and non-developed fish were analyzed separately. Fish that had tapeworms in the body cavity were similarly removed from the evaluation of the reproductive endpoint

Table 2.6: Description of Two-way ANCOVA Statistical Approach Applied to the Evaluation of Changes in Fish Health Endpoints in Koocanusa Reservoir Downstream (Elk River and Gold Creek) Study Areas Relative to Changes at the Upstream (Sand Creek) Study Area Over Time using Data Collected in 2014 to 2016

A two-way ANCOVA was used to compare endpoints between Elk River and Sand Creek study areas, and between Gold Creek and Sand Creek study areas. The model varied depending on data set properties and null hypotheses (H), as follows:

$Y=\beta0 + \beta1Cov + \beta2Area + \beta3Year + \beta4Area\times Year + \beta5Cov\times Area + \beta6Cov\times Year + \beta7Cov\times Area\times Year + \varepsilon$

H1: $\beta7=0$ (regression slopes are not dependent on area and year)
If $\beta7\neq0$ then regression slopes are dependent on area and year so ANCOVA conducted separately by year
If $\beta7=0$ then the Cov×Area×Year term was removed from the model and fit again.

$Y=\beta0 + \beta1Cov + \beta2Area + \beta3Year + \beta4Area\times Year + \beta5Cov\times Area + \beta6Cov\times Year + \varepsilon$

H2a: $\beta6=0$ (regression slopes are not dependent on year)
H2b: $\beta5=0$ (regression slopes are not dependent on area)
If $\beta5\neq0$ or $\beta6\neq0$ then regression slopes are dependent on area or year so ANCOVA conducted separately by year
If $\beta5=0$ and $\beta6=0$ then the Cov×Area and Cov×Year terms were removed from the model and fit again.

$Y=\beta0 + \beta1Cov + \beta2Area + \beta3Year + \beta4Area\times Year + \varepsilon$ (parallel slope model with Area×Year interaction)

H3: $\beta4=0$ (differences between areas in the covariate adjusted response are not dependent on year)
If $\beta4\neq0$ ANCOVA conducted separately by year
If $\beta4=0$ then Area×Year term was removed from the model and fit again.

$Y=\beta0 + \beta1Cov + \beta2Area + \beta3Year + \varepsilon$ (parallel slope model with no interaction)

H4: $\beta2=0$ (no difference between areas in the covariate adjusted response)
If $\beta2\neq0$ significant difference between areas (consistent difference among years)
If $\beta2=0$ no significant difference between areas (consistent difference among years)

ANCOVA conducted separately by year:

$Y=\theta0 + \theta1Cov + \theta2Area + \theta3Cov\times Area + \varepsilon$

H1: $\theta3=0$ (regression slopes are not dependent on year)
If $\theta3\neq0$ then regression slopes are dependent on area. Magnitude of difference reported for the minimum and maximum values of the overlap of covariate values
If $\theta3=0$ then Cov×Area term was removed from the model and fit again.

$Y=\theta0 + \theta1Cov + \theta2Area + \varepsilon$
H4: $\theta2=0$ (no difference between areas in the covariate adjusted response)

When a significant interaction was detected in the two-way ANCOVA model, then a one-way ANCOVA was conducted by year.

A significant Cov×Area×Year term implies that the regression slopes are dependent on area and year.

A significant Cov×Area term implies that the regression slopes are dependent on area.

A significant Cov×Year term implies that the regression slopes are dependent on year.

A significant Area×Year term implies that the difference between areas in the covariate adjusted response is dependent on year.

When none of these interaction terms are significant then the two-way ANCOVA can proceed and the area p-value is reported from the parallel slope model with no interaction.

* = significantly different at $\alpha = 0.1$
Magnitude of difference calculated as (downstream area-upstream area)/upstream area*100%

Results here are reported for all years together when there were no significant interactions.

Results are reported by year when there was a significant interaction.

When results were reported by year and regression slopes were significantly different between areas, results were reported as significant (*) and the magnitude of difference was estimated from predicted values of the regression at the minimum and maximum values of the range of overlap between areas.

Species	Sex	Response	Covariate	Significant Interactions[a]		Area P-value (Parallel Slope Model with No Interaction)	Elk River vs Sand Creek Area Comparisons[b]						Significant Interactions[a]		Area P-value (Parallel Slope Model with No Interaction)	Gold Creek vs Sand Creek Area Comparisons[b]					
							2014		2015		2016					2014		2015		2016

Peamouth Chub	M	log_{10}(Gonad Weight)	log_{10}(Adjusted Body Weight)	Cov×Year	0.008	-	-		-		* (17%)		Cov×Year	0.027	-	* (15%)	* (-2.2%)	-		* (42%)	* (-14%)
Peamouth Chub	F	log_{10}(Fork Length)	log_{10}(Age)	Area×Year	0.040	-	* (3.6%)		* (0.43%)		* (-1.9%)		Cov×Area×Year	<0.001	-	* (3.4%)		-		* (-2.9%)	
Peamouth Chub	F	log_{10}(Adjusted Body Weight)	log_{10}(Fork Length)	-	-	0.748	-						Area	-	0.006	* (-3.2%)					

[a] Significance of interaction terms assessed using $\alpha = 0.05$.
[b] Significance of Area comparisons assessed using $\alpha = 0.1$.
[c] Comparison of magnitude of difference conducted at the minimum and maximum values of the range of overvap of covariate values between areas when the regression slopes between areas within a year were not parallel.
* = significant difference (α=0.1) between areas (or a significant difference in regression slopes when a magnitude of difference is reported for the Min Cov and Max Cov)
N/A = no data

because the presence of worms has been shown to influence gonad development (Carter et al. 2005).

Data used to calculate fish health endpoints were plotted using scatterplots of the response variable versus the covariate, and using boxplots of the summary endpoints listed in Table 2.5. Statistical comparisons of fish health endpoints were conducted using a two-way ANOVA (as described in Section 2.2.3) for age, and using a two-way ANCOVA for the other endpoints.

The two-way ANCOVA was conducted with factors *Area* and *Year* when data were available for at least two years. For simplicity, comparisons were conducted separately for the Elk River downstream area relative to the Sand Creek upstream area, and for the Gold Creek downstream area relative to Sand Creek. The ANCOVA model varied depending on the comparisons of regression slopes between areas and among years. The ANCOVA analyses were conducted as described below.

A full interaction model was fit:

$$Y=\beta_0 + \beta_1 X + \beta_2 Area + \beta_3 Year + \beta_4 Area \times Year + \beta_5 X \times Area + \beta_6 X \times Year + \beta_7 X \times Area \times Year + \varepsilon$$

where Y is the response variable, X is the covariate, *Area* is a categorical variable for area, *Year* is a categorical variable for year, ε is the error term, and β_1 is the regression coefficient. The first hypothesis to test was whether the regression slopes were dependent on area and year:

H_{01}: $\beta_7=0$ (regression slopes were not dependent on area and year)

If the hypothesis H_{01} was rejected (i.e. $\beta_7 \neq 0$), then the regression slopes were dependent on area and year and the ANCOVA was conducted separately by year using a one-way ANCOVA. If the hypothesis H_{01} was not rejected (i.e. $\beta_7=0$) then the $X \times Area \times Year$ term was removed from the model and fit again:

$$Y=\beta_0 + \beta_1 X + \beta_2 Area + \beta_3 Year + \beta_4 Area \times Year + \beta_5 X \times Area + \beta_6 X \times Year + \varepsilon$$

The next hypotheses tested were whether regression slopes were dependent on area or dependent on year:

H_{02a}: $\beta_6=0$ (regression slopes were not dependent on year)
H_{02b}: $\beta_5=0$ (regression slopes were not dependent on area)

If hypothesis H_{02a} was rejected (i.e. $\beta_6 \neq 0$) then regression slopes were dependent on year and the ANCOVA was conducted separately by year using a one-way ANCOVA. If hypothesis H_{02b} was rejected (i.e. $\beta_5 \neq 0$) then regression slopes were dependent on area. With no differences between year, the interaction between the covariate and area could be evaluated by pooling years; however, for simplicity, the ANCOVA was conducted separately by year using a one-way ANCOVA when H_{02b} was rejected.

If hypotheses H_{02a} and H_{02b} were not rejected (i.e. $\beta_5=0$ and $\beta_6=0$) then the *X*×*Area* and *X*×*Year* terms were removed from the model and fit again:

$$Y=\beta_0 + \beta_1 X + \beta_2 Area + \beta_3 Year + \beta_4 Area \times Year + \varepsilon$$

The next hypothesis tested was whether differences between areas (in the covariate-adjusted response) were dependent on year:

H_{03}: $\beta_4=0$ (differences between areas in the covariate adjusted response were not dependent on year)

If hypothesis H_{03} was rejected (i.e. $\beta_4\neq0$), then differences in the covariate-adjusted response between areas was dependent on year, and the ANCOVA was conducted separately by year using a one-way ANCOVA. If hypothesis H_{03} was rejected (i.e. $\beta_4\neq0$) then the *Area*×*Year* term was removed from the model and fit again:

$$Y=\beta_0 + \beta_1 X + \beta_2 Area + \beta_3 Year + \varepsilon$$

The next hypothesis tested was whether there were differences between areas (in the covariate-adjusted response):

H_{04}: $\beta_2=0$ (no difference between areas in the covariate-adjusted response)

If hypothesis H_{04} was rejected (i.e. $\beta_2\neq0$), then differences in the covariate-adjusted response between areas was significantly different (and the magnitude consistent among years).

Two-way ANCOVAs were conducted using R (R Core Team 2015). When only a single year of data was available, analyses were conducted using ANOVA (for age) or ANCOVA with all three areas using Minitab 17 (Minitab 2015). When the overall ANOVA/ANCOVA was significant, comparisons of each downstream area to the upstream area were conducted using Dunnett's method.

All response variables and covariates were $\log_{10}$-transformed prior to conducting analyses. Outliers (i.e., observations with Studentized residuals with magnitude 4 or greater) were removed from analyses. Influential points (evaluated using the Cook's distance statistic) were removed from ANCOVA analyses when they caused significant interactions (Environment Canada 2012). Outliers and influential points are plotted in the scatterplots (Appendix F) as open symbols with an '×' through them. When a significant interaction was detected between the covariate and the *Area* term, but the coefficient of determination R^2 value of both the parallel regression model (interaction term) and full regression model were greater than 0.8 and within 0.02 units in value (Environment Canada 2012), slopes were considered practically parallel and the ANCOVA proceeded.

The magnitude of difference for the fish health endpoints was calculated as:

$$\text{MOD} = \frac{(\bar{X}_{DS} - \bar{X}_{US})}{\bar{X}_{US}} \times 100\%$$

where the $\bar{X}_{DS}$ and $\bar{X}_{US}$ are the means of the downstream area and upstream area, respectfully. The means used in the calculation for ANCOVA were least squares means from the ANCOVA model, back transformed (i.e. anti-logged) to the original data units. When a significant interaction between the covariate and the *Area* term was detected (i.e., the regression slopes between areas were different), the magnitude of difference was calculated for small fish and big fish (at the minimum and maximum values of the overlap of the range of covariate values between areas). Means used in the calculation of the magnitude of difference were the predicted values of the response variable at the minimum and the maximum values of the covariate overlap based on the regression lines for each area (Environment Canada 2012).

2.6.4.2 Tissue Chemistry

Metal toxicity is usually assessed on the basis of measured waterborne exposure concentrations, sometimes by also taking into account environmental factors that affect metal interaction with biological tissues (e.g., biotic ligand models; DiToro et al. 2001), or by assessment of effects in direct or simulated exposure scenarios (e.g., *in situ* or laboratory bioassays, field studies) (Chapman et al. 1998; Environment Canada 2012). With few exceptions (e.g., mercury, selenium), the potential for toxicity to biota related to metal exposure in aquatic environments is not well predicted by concentrations measured in their tissues (Chapman and Wang 2000, McGeer et al. 2003, Deforest et al. 2007, Meador et al. 2010, Adams et al. 2011). Therefore, for most metals, concentrations in tissues are of limited utility in evaluating effects on the biota from which the tissues are collected. Results of a recent screening-level risk assessment also concluded that from the nine constituents evaluated, selenium was the only known mine-related substance of potential concern with respect to the Elk River watershed (Windward 2015). For these reasons, the tissue chemistry assessment focuses on selenium. Evaluation of differences in mercury concentrations in fish tissues among sampling areas was also included. The remainder of tissue metals data are provided in Appendix G, but are not discussed within this report.

Selenium concentrations in fish tissues were statistically compared between the downstream areas (Elk River and Gold Creek) and the upstream area (Sand Creek) from 2014 to 2016. Selenium concentration data were combined for muscle collected from a species within a given year, while whole body and ovary selenium concentrations were only collected in April. Selenium concentrations in fish tissues were also plotted and compared to the BCMOE guidelines (for muscle, ovary, and whole body), the 2016 United States Environmental Protection Agency (USEPA) guidelines (for muscle, ovary, and whole body), and the EVWQP

Level 1 benchmark for reproductive effects (ovary tissues only). Mercury concentrations in fish muscle relative to length were tested using linear regression (data from all study areas and years combined for each species) and compared to the BC tissue residue guideline for the protection of wildlife (BCMOE 2017a).

3 WATER QUALITY

3.1 Overview

In accordance with Permit 107517, water quality is monitored weekly (March 15th to July 15th) or monthly (remainder of the time when reservoir access is not restricted by safety concerns related to ice cover and flowing water) by Teck at five stations within the reservoir, including one situated upstream from the Elk River (initially at RG_USELK and then moved farther upstream to RG_KERRRD in April 2015) and four downstream from the Elk River (RG_DSELK, RG_GRASMERE, RG_USGOLD, RG_BORDER; Figure 2.1). At each station, water temperature, DO, pH, specific conductance, and Secchi depth are measured *in situ*, and samples are collected for laboratory analysis of nutrients, major ions, metals, TSS, turbidity, and other conventional parameters. Depth permitting, three samples (surface, mid-column and bottom) were collected under un-stratified conditions[6], one at 3 m from the surface, one 3 m from the substrate, and one at the mid-point of the water column. If the water was too shallow to allow for the collection of three samples, a single surface sample, or both a surface and bottom sample were collected. Data are reported annually (e.g., Teck 2016b, 2017). Station RG_DSELK is an Order station, at which SPO for cadmium, nitrate, selenium, and sulphate apply.

In association with biological sampling for the current study, *in situ* measurements of water quality were completed in February, April, and August, 2014 to 2016. Measurements were made at two transects, one each located upstream versus downstream of the Elk River where sediment, plankton, and benthic invertebrate samples were collected (T2/TN[7] and T4, respectively, five stations per transect sampled in August), and at three areas where fish were collected (near Sand Creek, Elk River and Gold Creek, sampled in February, April, and August).

3.2 *In Situ* Water Quality Profiles

Within-year water temperature profiles in August (i.e., maximum annual water depths) were similar between the areas downstream versus upstream of the Elk River (Figure 3.1). Greater variation was observed among years, but a decreasing gradient in water temperature was observed at depths below 6-10 m from the surface in all years. Profiles completed in February and April, when water levels were lower (Figure 1.2), showed very little change in temperature

[6] Under stratified conditions, different sampling instructions would apply but the associated condition was not encountered.

[7] As noted in Section 2.1, transect T2 was moved farther upstream to TN in August 2015 to correspond with the relocation of water station RG_USELK to RG_KERRRD, thereby avoiding influence from the Elk River.

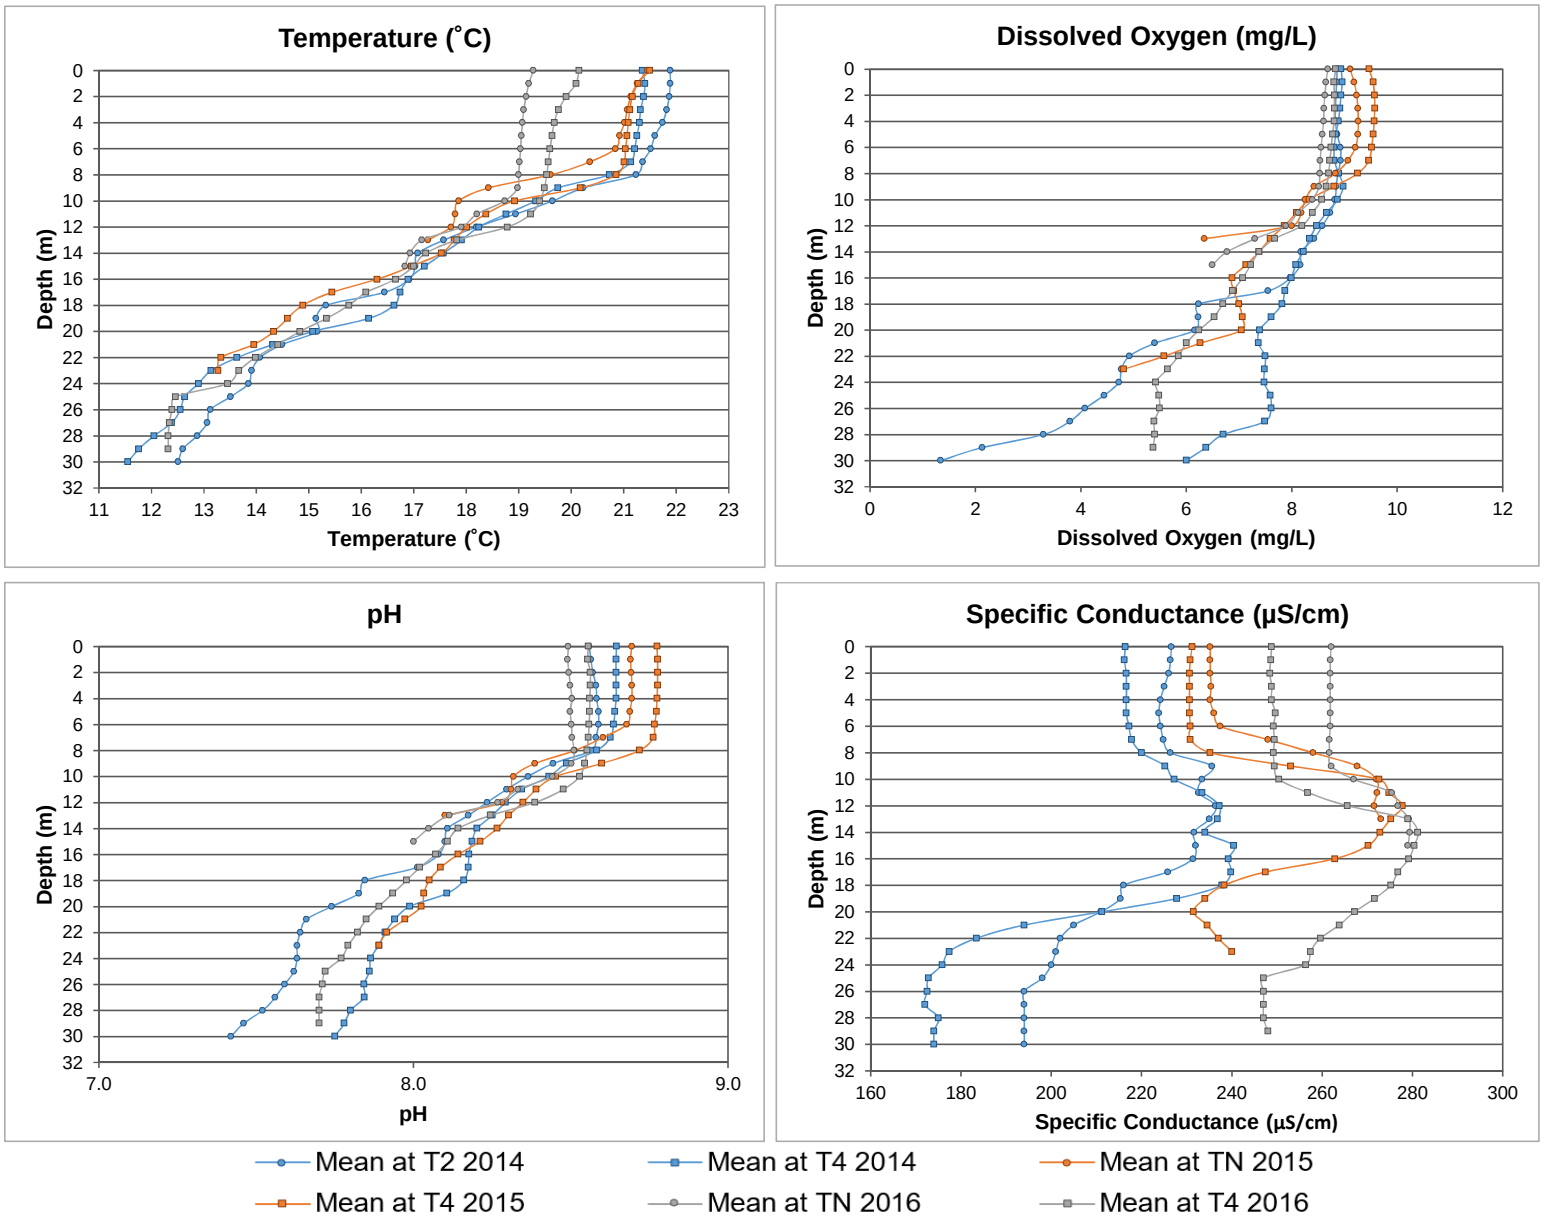

Figure 3.1: Mean (n=5 Stations per Area) *In Situ* Water Quality Profiles Measured at Stations Downstream (T4) and Upstream (T2/TN) of the Elk River in Koocanusa Reservoir, August 2014, 2015, 2016

with depth (Appendix Figures B.1 to B.3 and Tables B.1 to B.3). Surface water temperatures were higher at all stations in April 2015 compared to April 2014 and 2016 (Appendix Figure B.2).

A decreasing concentration gradient with depth, beginning 8-10 m below the surface, was also observed for DO, with similar profiles in August between the upstream and downstream areas, except in 2014. In August 2014, the DO concentrations were lower at the upstream transect (e.g., 4.1 mg/L at 26 m [at station T2-2]) compared to downstream (mean 7.6 mg/L at 26 m) (Figure 3.1). Therefore, although some values were less than the BC long-term water quality guideline for protection of aquatic life (8.0 mg/L) and some were also less than the instantaneous minimum value (5.0 mg/L), this did not occur as a result of influence from the Elk River. February and April profiles indicated DO concentrations of 10 mg/L or more at all areas, except at the deepest part (i.e., 10 to 12 m below surface) of the upstream Sand Creek area in February 2014, where concentrations as low as 4.5 mg/L were observed (Appendix Figures B.1 and B.2).

Aqueous pH was slightly alkaline (range of 7.2 to 8.8) in all sampling areas and at all depths (Figure 3.1; Appendix Figures B.1 to B.3 and Tables B.1 to B.3). As observed for temperature, a gradient of decreasing pH was evident in August at depths of more than 8 to 10 m below the surface and varied little among areas or years (Figure 3.1). Aqueous pH was consistently within the BC water quality guideline range of 6.5 to 9.0 (Appendix Tables B.1 to B.3).

Specific conductivity (i.e., conductivity standardized to a temperature of 25°C) varied among depths, sampling areas, and years (Figures 3.1; Appendix Figures B.1 to B.3 and Tables B.1 to B.3). August profiles taken at transects both upstream (T2/TN) and downstream (T4) of the Elk River showed increasing conductivity mid-water-column (e.g., 6-16 m) and then decreasing values at greater depths (Figure 3.1). At reservoir areas closer to Sand Creek, Elk River, and Gold Creek mouths (i.e., fish collection areas), the August profiles indicated an increase with depth (Appendix Figure B.3). Within years, specific conductivity in August was consistently lower downstream compared to upstream in the upper part of the water column, but values overlapped in deeper waters (>10 m). Profiles in February and April showed little change in specific conductance with depth, except for lower values within the top 1 m in February (Appendix Figure B.2). Elk River has greater specific conductivity (annual mean of 342 µS/cm at RG_ELKMOUTH) than the lower Kootenay River (annual mean of 264 µS/cm at RG_WARDB) (Appendix Tables B.10 and B.11). Previous studies have reported that inflow temperatures from the Elk and Kootenay River correspond best with temperatures at mid to bottom depths of the reservoir, so this is where densities would be most similar and river inflows would thus be expected to occur during most of the year (Hamilton et al. 1990). The same authors reported that the Canadian portion of the reservoir remains mixed even during full pool,

as a result of basin morphometry, continual movement of water from dam operations and exposure to strong prevailing winds. More recent water sampling at Teck's five stations within the reservoir showed no instances of stratification in 2016, some stratification (i.e., one time at RG_BORDER and RG_USGOLD) in August 2015, and multiple times from June 25th to September 3rd in 2014 (i.e., four times at RG_GRASMERE, three times at RG_USELK, RG_DSELK, and RG_EASTARM, and two times at RG_BORDER).

3.3 Water Quality Based on Laboratory Sample Analyses

3.3.1 Statistical Evaluations

Plots of Order constituents nitrate, selenium, and sulphate suggested that aqueous concentrations may differ between surface, middle, and bottom layers sampled in the latter half of the year when reservoir water levels are highest (Appendix Figures B.4 to B.6). Dissolved cadmium (also an Order constituent) was omitted from the analysis, as most concentrations were less than the method detection limits as discussed in Section 2.2.3 (Appendix Tables B.4 to B.9).

Statistical tests identified significant differences in aqueous concentrations of nitrate, selenium, and/or sulphate between samples collected at the surface compared to lower depths at most stations (Table 3.1). However, concentrations were not significantly different between samples collected at the middle versus bottom depths at any stations, except for a small difference (2.5%) for sulphate at the upstream RG_KERRRD station. At stations downstream from the Elk River, nitrate, selenium, and sulphate concentrations were typically lower at the surface, but there was some variation in patterns among years (Table 3.1 and Figures 3.2 to 3.4).

Based on the results of Table 3.1, data for middle and bottom samples were averaged within months, and annual means were statistically compared among areas for middle-bottom samples separately from surface samples. Nitrate concentrations at both surface and middle-bottom depths of the water column were significantly higher at stations downstream from the Elk River compared to upstream in 2015 and 2016 (Table 3.2). Results were less consistent in 2014 when the upstream station was situated closer to the Elk River. The difference between upstream and downstream concentrations was greater in 2016 than 2015 for both nitrate and selenium, but mean concentrations at downstream areas in 2016 were similar to or less than those observed in 2015 (Table 3.2). Sulphate concentrations did not differ significantly between Koocanusa Reservoir stations located downstream versus upstream of the Elk River in any years (Table 3.2).

Table 3.1: Statistical Summary of Differences in Nitrate-Nitrogen, Total Selenium and Sulphate Concentrations between Surface and Middle, Surface and Bottom, and Middle and Bottom Depths in the Water Column at Individual Koocanusa Reservoir Stations Based on Routine Water Quality Monitoring Samples Collected in 2014 to 2016 (all years combined)

Station		Nitrate-N			Total Selenium			Sulphate		
		Surface versus Middle	Surface versus Bottom	Middle versus Bottom	Surface versus Middle	Surface versus Bottom	Middle versus Bottom	Surface versus Middle	Surface versus Bottom	Middle versus Bottom

K-W = Kruskal-Wallis test; WSRT = Wilcoxon signed rank test; t-test = one sample t-test; M-W = Mann Whitney test; ANOVA = Analysis of Variance.

NA= not applicable (no data for RG_USGOLD in 2014)

3.3.2 Comparisons to Guidelines and SPOs

Annual water quality results for samples collected in Koocanusa Reservoir in 2015 and 2016[8] identified very few exceedances of the MOE guidelines for protection of aquatic life (Teck 2016b, 2017). Guideline exceedances were reported for aluminum (one sample at RG_DSELK in 2015), iron (one sample at RG_GRASMERE in 2015 and one sample at RG_DSELK in 2016), and mercury[9] (5 samples at RG_DSELK in 2016). Concentrations of nitrate, selenium, sulphate, and dissolved cadmium were consistently below SPOs at RG_DSELK in both years (Figure 3.5).

[8] No annual report was provided for 2014 because Permit 107517 was not in effect until late November 2015. As such, water quality reporting was completed under previous mine operational permits.

[9] The BC water quality guideline for mercury is based on the percent of methyl mercury present and, in the absence of methyl mercury data for all stations, Teck has applied the most stringent mercury guideline (which assumes that a large proportion of total mercury is present as methyl mercury). Teck recently began sampling for methyl mercury, and 48 methyl mercury samples collected in 2016 throughout the Elk Valley had methyl mercury concentrations less than the method detection limit of < 0.000050 µg/L. Assuming continued monitoring corroborates these results, it is expected that future water quality evaluations will confirm no mine-related exceedances of the appropriate mercury guideline, and metallurgical coal mining is not a source of mercury to the receiving environment.

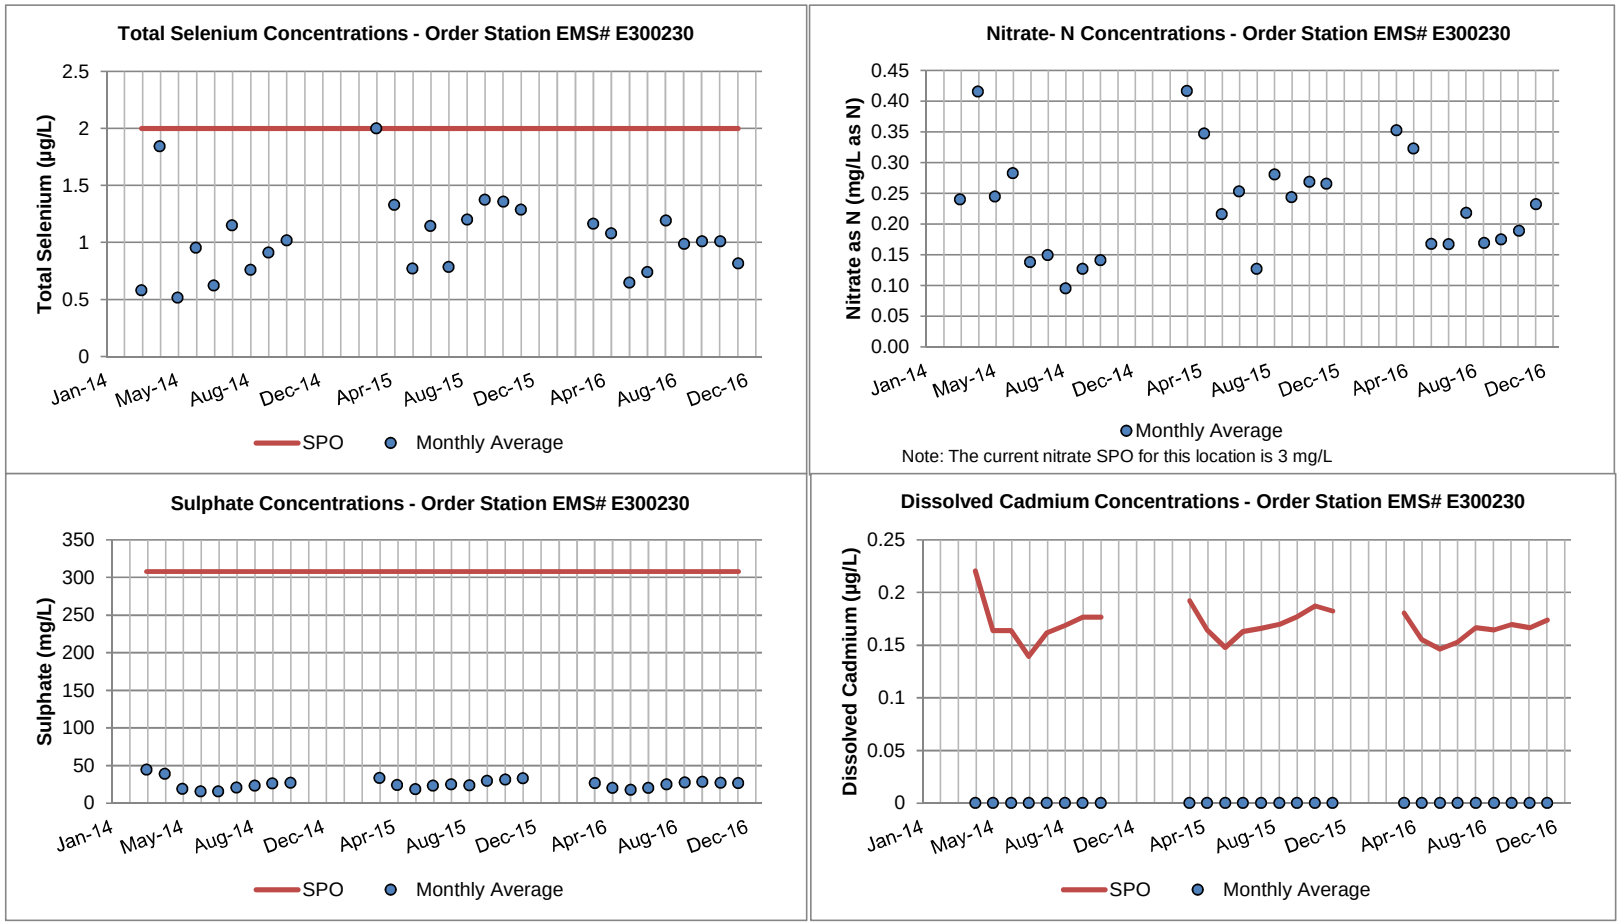

Figure 3.5: Monthly Average Concentrations of Order Constituents Relative to Site Performance Objectives Recorded at Order Station RG_DSELK, Koocanusa Reservoir, 2014 to 2016

4 SEDIMENT QUALITY

4.1 Overview

Sediment samples were initially collected in Koocanusa Reservoir in April 2013, when seven transects were sampled across the Canadian portion of the reservoir, two upstream and five downstream of the Elk River confluence (Minnow 2014a). In August 2013, following record flooding in the Elk River watershed in June 2013, Transects T2 and T4 were re-sampled to further characterize sediment quality. Subsequent sampling of sediment, plankton, and benthic invertebrates in the three-year (2014 to 2016) Koocanusa Reservoir monitoring program (described herein) focused on two transects (i.e., T2 and T4). As noted in Section 3.1, the upstream transect (T2) was re-located 3.5 km farther upstream in August 2015 (TN) to avoid influence from the Elk River (Figure 2.1). Sediment samples were collected in August of all three years from five stations along each transect (Appendix Tables C.1 to C.3).

4.2 Results

Sediment samples collected in the reservoir downstream and upstream from the Elk River were mostly silt (60-82%), with sand and clay comprising smaller fractions (Figure 4.1; Appendix Tables C.4 to C.6). Sediments collected along the transect upstream from the Elk River (T2/TN) were consistently significantly sandier (annual means of 2-10%) with less clay (means of 17-19%), than those collected downstream at transect T4 (means of <1% for sand and 26-30% for clay), which may be related to the shallower depths and more fluvial nature of the reservoir at T2/TN (i.e., greater seasonal scour resulting in finer particles accumulating in sediments farther downstream) (Table 4.1). TOC content ranged from 0.9 to 1.7%, comparable to a mean TOC of 1.1% reported for Koocanusa Reservoir sediments by Iskandar and Shukla (1981), which was considered low and indicative of oligotrophy. A small difference in sediment TOC was observed between areas in 2015 (i.e., 1.6% versus 1.2% downstream compared to upstream) but TOC concentrations were not different between areas in 2014 or 2016 (Appendix Table C.7).

Concentrations of most metals and PAHs were significantly higher in sediments collected downstream from the Elk River compared to upstream (Table 4.1; Figure 4.2; Appendix Table C.7). Larger downstream-to-upstream differences in selenium and mercury concentrations were observed in 2016 compared to previous years, but only selenium showed a slight increase in concentrations over the three-year period. Downstream of the Elk River, all analytes other than selenium were found at similar or lower mean concentrations in 2016 compared to 2015. Even for selenium, the change in mean concentration over the three years was small (0.52, 0.66, and 0.68 mg/kg dw in 2014 to 2016 respectively), and mean

* indicates a significant difference between the two areas at an α of 0.1.

[a] Data are summarized for analytes that had mean concentration greater than the low BC Sediment Quality Guideline in at least one area and year (plus selenium). See Appendix Table C.7 for results for all other analytes.

[b] The measure of central tendency reported is based on the applied data-transformation, as follows: mean for no transformation; geometric mean for $\log_{10}$-transformation; and, median for rank-transformation.

[c] The bolded values are above BC Sediment Quality Guidelines lowest effect level.

[d] Interim Sediment Quality Guideline (ISQG; or Threshold Effect Level [LEL])/ Probable Effect Level (PEL)

[e] Lowest Effect Level (LEL)/ Severe Effect Level (SEL).

p-value < 0.1.

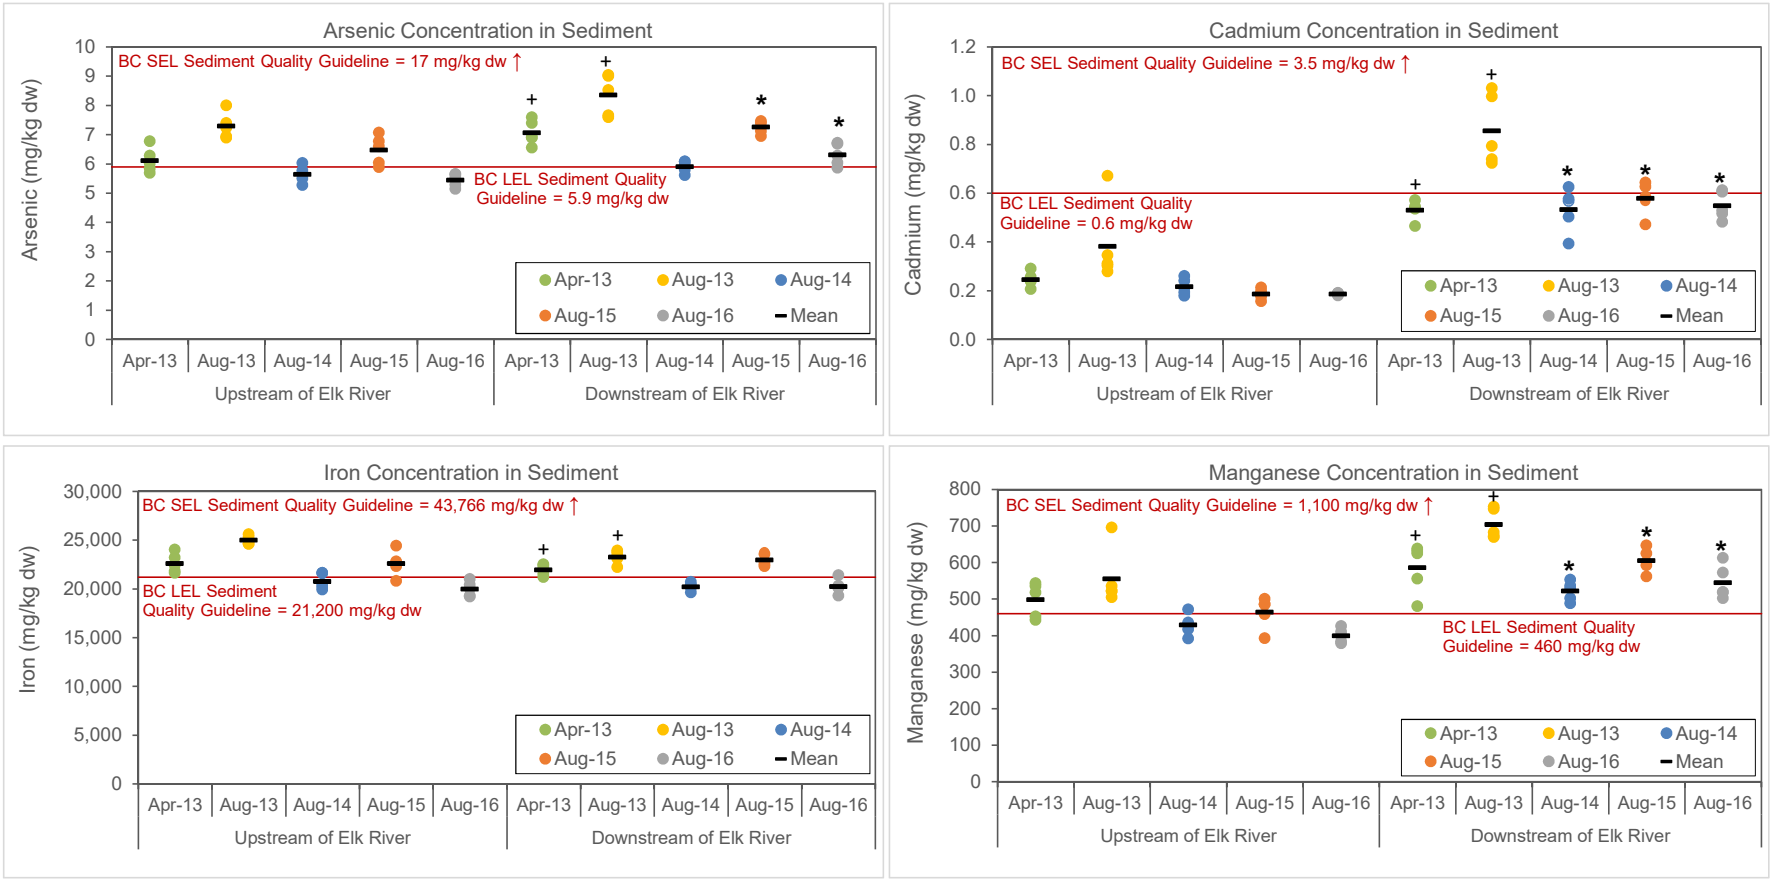

Figure 4.2: Concentrations of Selected Parameters in Sediment Samples from Koocanusa Reservoir, 2013 to 2016

Notes: The upstream location was relocated further upstream from the mouth of the Elk River in August 2015 and 2016. Concentrations below the MDL are plotted as open symbols (associated number indicates number of samples with parameter concentrations below MDL) at the MDL concentration.
' * ' indicates the downstream area was significantly different from the upstream area in the same year.
' + ' indicates that no statistical analysis was not completed with these data (i.e., sediment collected in 2013).

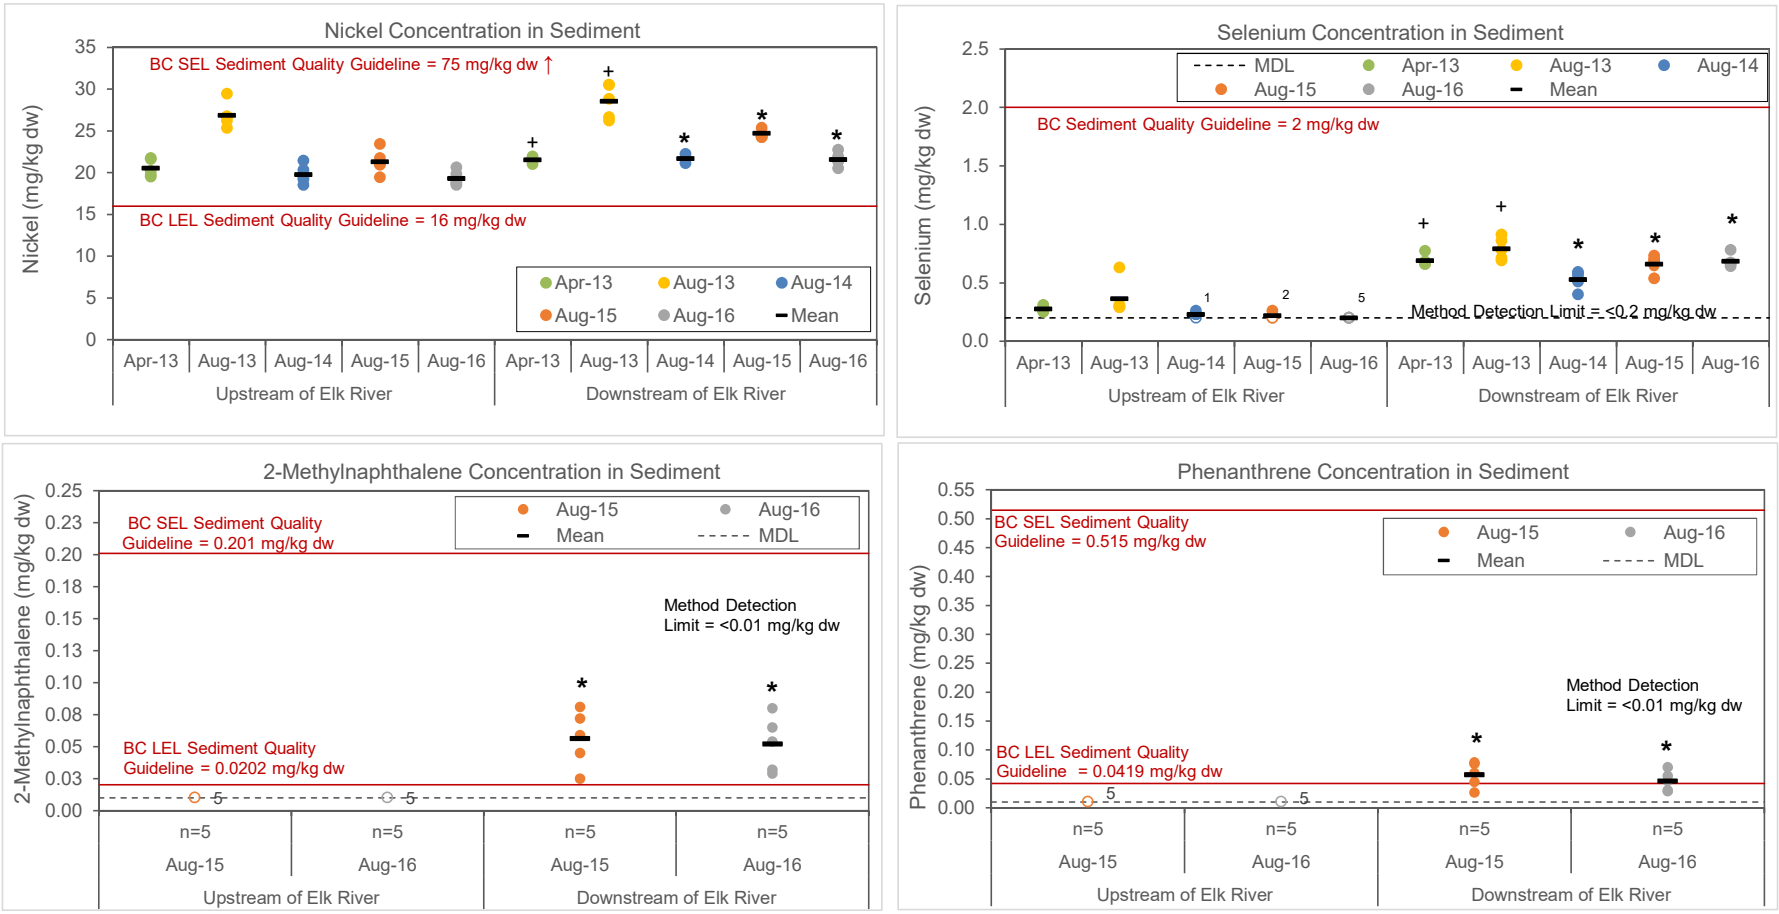

Figure 4.2: Concentrations of Selected Parameters in Sediment Samples from Koocanusa Reservoir, 2013 to 2016

Notes: The upstream location was relocated further upstream from the mouth of the Elk River in August 2015 and 2016. Concentrations below the MDL are plotted as open symbols (associated number indicates number of samples with parameter concentrations below MDL) at the MDL concentration.
' * ' indicates the downstream area was significantly different from the upstream area in the same year.
' + ' indicates that no statistical analysis was not completed with these data (i.e., sediment collected in 2013).

concentrations observed at the downstream area in 2014 to 2016 were less than those measured in 2013 (Figure 4.2). Concentrations of some metals and PAHs in sediments were above the corresponding low sediment quality guideline, but none exceeded the high guideline (Appendix Tables C.4 to C.7). Concentrations of all PAHs in sediment were less than the method detection limit at stations in the upstream (TN) sampling area (Appendix Tables C.5 to C.6). Average concentrations of 2-methylnaphthalene and phenanthrene were greater than the low sediment guideline downstream of the Elk River, but were well below the high sediment quality guidelines (Figure 4.2). In addition, mean concentrations of Order constituents[10] cadmium and selenium were less than the sediment quality guidelines (Table 4.1; Figure 4.2).

Mean concentrations of arsenic, iron, manganese, and nickel in sediment were also above the low, but not high, sediment quality guidelines in at least one of the three monitoring years, including the upstream area (Table 4.1; Figure 4.2). The general pattern observed of higher concentrations of metals in sediment downstream of the Elk River in comparison to upstream may be related to the greater proportion of fine sediment particles in the downstream area. This point is also supported by data for samples collected in August 2013, when the percentage of fine particles and also the concentrations of many metals increased downstream from the Elk River relative to samples collected in April of that year as a result of sediment transport and deposition during record storm in June 2013 (Figure 4.2; Minnow 2014a). Fine particles provide more surface area relative to volume than larger particles, so sediments having finer particles are more likely to have elevated concentrations of chemicals that adsorb to particle surfaces than areas with larger particles (Horowitz and Elrick 1987; Blanton et al. 1995).

[10] See section 1.2 for explanation of the Provincial Order and associated constituents of concern.

5 PLANKTON AND PRODUCTIVITY

5.1 Overview

Nitrogen species (nitrate, nitrite, ammonia), phosphorus species (total phosphorus, ortho-phosphate), chlorophyll-a, and Secchi depth are measured as part of Teck's routine water quality monitoring at stations in Koocanusa Reservoir based on grab samples collected at surface, middle, and bottom depths (Section 2.2.1). The data were summarized to evaluate trophic status (productivity).

Chlorophyll-a concentrations were also measured along the same transects where sediment samples were collected, along with seston biomass (another indicator of plankton productivity) in August of each of the three study years. These were based on depth-integrated samples collected from the top 10 m of the water column to provide an average value for each station along each transect (n=5 samples per transect). Chlorophyll-a was also measured *in situ* in 2015 to investigate variability in concentrations at 1 m depth intervals and to test the accuracy of the method by comparing average *in situ* concentrations over the top 10 m to those reported by the laboratory for the 10 m depth-integrated samples.

Phytoplankton and zooplankton community structure, and zooplankton tissue selenium concentrations, were also assessed based on samples collected from the same areas in August of each year.

5.2 Productivity

5.2.1 This Study

Ratios of total nitrogen to total phosphorus concentrations (N:P) greater than 15 indicate that phosphorus is the limiting nutrient based on categories defined by McDowell et al. (2009) for mass concentrations:

- N:P < 7 Nitrogen-limited
- 7 < N:P < 15 Co-limited (nitrogen and phosphorus)
- N:P > 15 Phosphorus-limited.

Based on concentrations measured in Koocanusa Reservoir as part of Teck's water quality monitoring program, median ratios were found to be 15 or more (Figure 5.1), which suggests that phosphorus is limiting, especially at stations downstream from the Elk River. Phosphorus was also concluded to be the limiting nutrient in previous studies of the reservoir (Hamilton et al. 1990; Richards 1997).

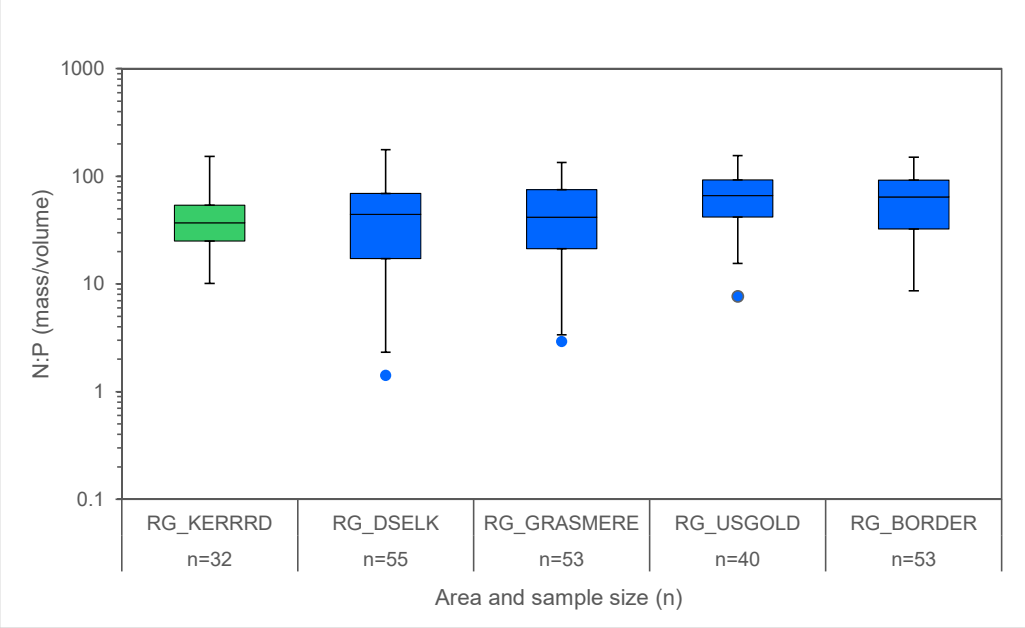

Figure 5.1: Boxplot of Ratios of Nitrate to Total Phosphorus Mass Concentrations for Samples Collected in Koocanusa Reservoir, 2014 to 2016

Note: The box represents the 25th percentile, median, and 75th percentile and the whiskers represent the minimum and maximum values; however, values 1.5 times the height of the box beyond the 25th and 75th percentiles are plotted as individual values in which case the whisker is truncated to the next value in the data set.

Phosphorus concentrations measured in the lower Elk River (RG_ELKMOUTH) were similar to those measured in the lower Kootenay River (RG_WARDB) (Appendix Tables B.10 and B.11), as was reported by Hamilton et al. (1990). However, flows in the Kootenay River are about three times higher, on average, than those in the Elk River (Appendix Figures B.13 and Table B.12; Hamilton et al. 1990).

Concentrations of total phosphorus and ortho-phosphate were highest in early spring and generally decreased through the remainder of the year, with ortho-phosphate concentrations usually undetectable (<0.0010 mg/L) in the latter part of the year (Appendix Figures B.7 and B.8). Secchi depths generally increased during the ice-free period (Appendix Figure B.9), which is contrary to the expected relationship of decreasing Secchi depth with increasing biological productivity in warmer months (Tilzer 1988). Low spring Secchi depths were likely related to high concentrations of TSS associated with freshet (Appendix Figure B.11) causing reduced water transparency (Tilzer 1988; Wetzel 2001). Concentrations of chlorophyll-a varied seasonally, with minima typically occurring in April or early May, consistent with low water levels, cooler temperatures, and high turbidity/TSS. This was followed by an increase in chlorophyll-a through the summer months. Secchi depths increased as water level rose and

TSS concentrations declined, but sometimes dipped again in July or August (Appendix Figure B.9), likely corresponding with peak primary productivity (Tilzer 1988). Finally, Secchi depth increased again toward November as both water temperatures and productivity decreased. As would be expected, chlorophyll-a concentrations were typically higher in samples collected at the surface compared to deeper samples (Appendix Figure B.10).

Chlorophyll-a concentrations measured *in situ* in August 2015 varied little with depth, except near Gold Creek where maxima were observed at 7-8 m in both April and August, and near Sand Creek in August only (maximum concentration at 4 m; Appendix Figure D.1). Profiles confirmed that depth-integrated water samples collected over the top 10 m captured most of the variation in chlorophyll-a concentrations among areas. However, *in situ* measurements of chlorophyll-a were consistently lower than concentrations reported by the laboratory (Appendix Figure D.2), so *in situ* measurements were not continued in 2016.

Chlorophyll-a concentrations reported by the laboratory for depth-integrated samples were significantly higher downstream from the Elk River than upstream in all three years, and the magnitude of difference increased slightly each year (Table 5.1, Figure 5.2, Appendix Table D.1 and Figure D.2). However, mean chlorophyll-a concentrations in depth-integrated samples were consistently low (see categories in Table 2.5), ranging between 1.7 and 3.0 µg/L among areas and years (Table 5.1). Chlorophyll-a concentrations measured in surface and middle-bottom samples as part of Teck's routine water quality monitoring were similarly low (i.e., usually < 3 µg/L; Appendix Figure B.10 and Tables B.5 to B.9).

Total seston biomass in depth-integrated samples collected in August of each year was significantly higher (35%) downstream (T4) of the Elk River compared to upstream (TN) in 2016, but did not differ significantly between areas in either 2014 or 2015 (Table 5.1; Appendix Table D.1). Mean seston biomass was lowest at both areas in 2015 (Figure 5.2).

5.2.2 Comparison to Previous Studies

Previous studies of limnological processes in Koocanusa Reservoir reported a weak thermal structure leading to a hypothesis that phytoplankton was circulated out of the euphotic zone. Such circulation was verified by a study of chlorophyll-a distribution, which revealed that more than one-half of the reservoir's phytoplankton was located beneath the euphotic zone (Woods 1982).

The post-impoundment primary productivity levels have been characterized as ultra-oligotrophic to mesotrophic as a result of the impoundment as well as channelization, diking, and pollution abatement measures in the watershed (Woods 1982, Woods and Falter 1982, Richards 1997). The low chlorophyll-a concentrations and seston biomass observed in this study were

Table 5.1: Statistical Summary of Spatial and Temporal Differences in Seston Biomass and Chlorophyll-a Concentrations in Koocanusa Reservoir in the Area Downstream from the Elk River (T4) Compared to the Upstream Area (T2/TN), 2014 to 2016

Parameter	Trans-formation	Measure of Central Tendency (Mean, Geometric Mean, or Median)[a]						Model P-values			Contrasts			Significant Differences and Magnitudes of Difference (%)		
		2014		2015		2016					Area × Year

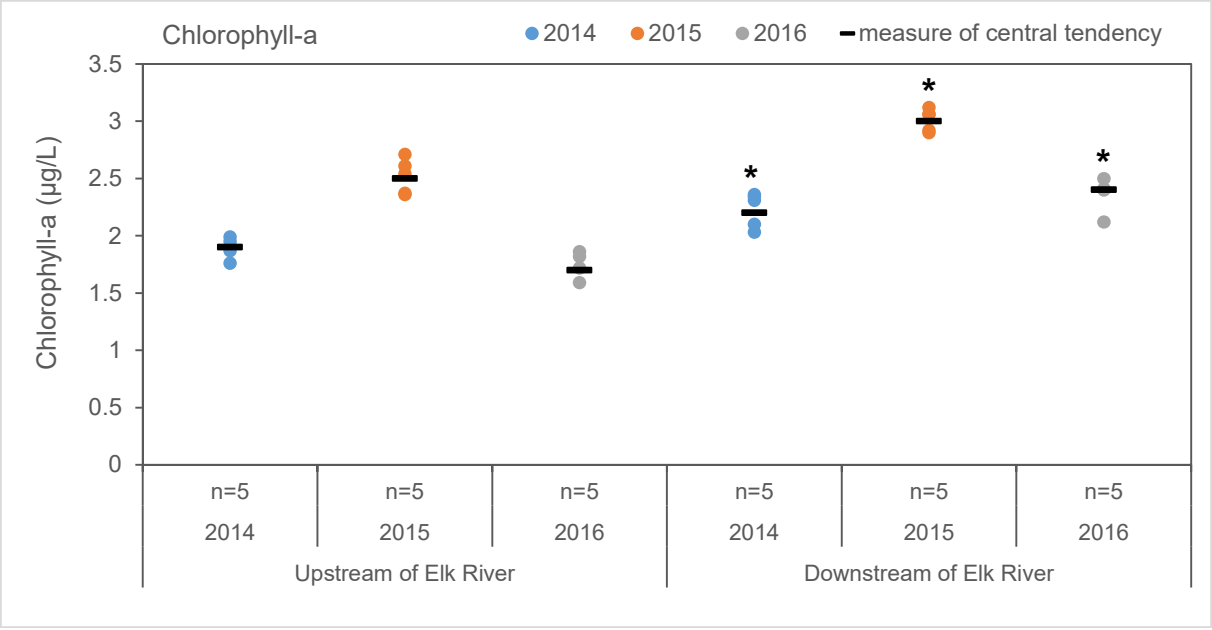
p-value < 0.1.

* indicates a significant difference between the two areas at an α of 0.1.

[a] The measure of central tendancy reported is based on the applied data-transformation, as follows: mean for no transformation; geometric mean for log $_{10}$-transformation; and, median for rank-transformation.



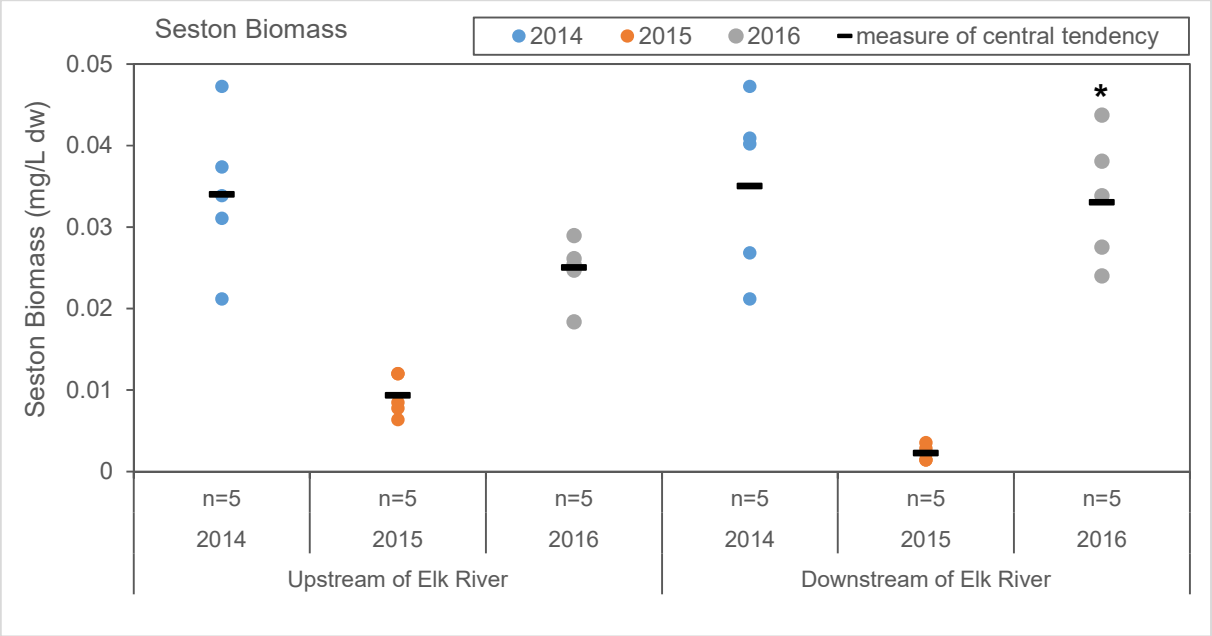


Figure 5.2: Seston Chlorophyll-a (µg/L) and Seston Biomass (mg/L dw) in Koocanusa Reservoir, August 2014 to 2016

Notes: The upstream location was relocated further upstream from the mouth of the Elk River in August 2015 and 2016.

' * ' indicates the downstream area was significantly different from the upstream area in the same year.

consistent with observations from the 1980s (1.0-2.0 µg/L for chlorophyll-a and < 0.1 mg/L for biomass; Hamilton et al. 1990). Although shallow Secchi depths observed in recent monitoring suggested a higher trophic classification, phosphorus and chlorophyll-a concentrations support

an oligotrophic classification (Table 5.2), consistent with the conclusions of Woods (1982) and Richards (1997). As noted above, the pattern of lowest Secchi depths in spring months is attributable to greater concentrations of TSS during freshet (Appendix Figure B.11), rather than elevated biological productivity. Highest biological productivity in the reservoir occurs in July and August when surface water is warmest and the euphotic zone is maximal (Hamilton et al. 1990, Richards 1997). Woods (1979) concluded that the dominant influence on primary production in Koocanusa Reservoir was light quantity, which is controlled by at least three factors: thermal structure which allows phytoplankton to be circulated out of the euphotic zone, elevated turbidity during spring runoff (freshet), and seasonal and meteorological variations in incident solar radiation.

5.3 Phytoplankton Community Structure

Phytoplankton communities in Koocanusa Reservoir both upstream (T2/TN) and downstream (T4) of the Elk River were numerically dominated by diatoms (algae with cell walls of hydrated silica) in all study years, with chrysophytes (golden algae) also being relatively abundant at both areas in 2014 and 2016 (Table 5.3, Figure 5.3; Appendix Tables D.2 to D.28 and Figures D.3 to D.6). Density and biomass of all other groups were variable, typically comprising 0-5% of the community (Table 5.3).

At the species level, the centric diatom *Cyclotella pseudostelligera* dominated the phytoplankton communities both upstream and downstream of the Elk River in all three years in terms of absolute and relative density and biomass (Figure 5.4; Appendix Tables D.1 to D.25). The predominance of *C. pseudostelligera* in Koocanusa Reservoir in August potentially reflects flow from the tributaries near each sampling area, which may provide the upwelling necessary to prevent individual organisms from sinking out of the photic zone and supplying the silica/silicon/silicates for frustule formation (H. Larratt, pers. comm. 2016). In addition, the relatively low nutrient concentrations within Koocanusa Reservoir (Section 5.2) may prevent *C. pseudostelligera* from being outcompeted by other organisms such as blue-green algae, which prefer higher concentrations of nitrogen and phosphorus (i.e., more eutrophic conditions; H. Larratt, pers. comm. 2016).

No significant differences in overall phytoplankton density, biomass, or richness were indicated between downstream and upstream areas over the three years (Table 5.3; Figure 5.5). In addition, there were no consistent downstream-to-upstream differences in abundance or relative biomass of major phytoplankton groups (i.e., Chlorophyte, Chrysophyte, Diatom, Cryptophyte, Dinoflagellate) among years. The exception was Cyanophyte biomass which was consistently higher at the downstream area compared to the upstream area in all three years. This group represented a very small proportion of the community (<1%; Table 5.3) suggesting low

ecological relevance. Overall phytoplankton community composition, as summarized by NMDS, did not differ between upstream and downstream areas within each of the three years, but varied among years (Figure 5.6; Table 5.3, Appendix Tables D.26 to D.28. Large year-to-year variation in the percent composition of major algal groups was observed from 1975 to 1988 (Hamilton et al. 1990).

5.4 Zooplankton

5.4.1 Community Structure

The zooplankton community in Koocanusa Reservoir was numerically dominated by rotifers and copepods, with relatively low numbers of cladocerans (Table 5.4, Figure 5.7; Appendix Tables D.29 to D.55 and Figures D.7 to D.10). However, the smaller size of rotifers resulted in a considerably lower relative biomass compared to copepods. Consequently, copepods dominated the zooplankton community biomass both upstream and downstream from the Elk River in all three years, except at the upstream area in 2016, when cladocera were dominant (Table 5.4). The numerically dominant taxa (i.e., those representing >5% of the community at one or more stations in each year) were similar between areas in each year, but varied among years (Figure 5.8). No consistent differences were observed between downstream and upstream areas in overall zooplankton density, biomass, or richness, or in absolute or relative density or biomass of copepods or rotifers, over the three years of study (Table 5.4; Figure 5.9). Absolute and relative cladoceran density and biomass were lower at the downstream area compared to upstream in all three years (absolute density and biomass), or in the latter two years (relative density and biomass). Some cladocerans are predacious, but most species are herbivorous and feed on phytoplankton, organic matter, and bacteria. As described in Sections 5.2 and 5.3, phytoplankton density and biomass were similar between downstream and upstream areas; and chlorophyll-a was higher downstream compared to upstream, suggesting that fewer cladocerans downstream of the Elk River was likely not due to food limitations.

Most variability in overall zooplankton community structure was captured on NMDS-Axis 1 (91.7%) and organisms contributing to the separation of areas along Axis-1 included a variety of copepods, cladocerans, and rotifers (Figure 5.10; Appendix Tables D.53 to D.55). Stations at the downstream area had more positive scores on NMDS-Axis 1 in 2014 and 2015 and more negative scores in 2016, compared to the upstream area, indicating that community differences between upstream and downstream areas were likely not associated with influence from the Elk River. The largest changes in community structure were associated with sampling year with no overlap in community structure between any of the three years on NMDS-Axis 1 (Figure 5.10). Differences between the downstream and upstream areas of the Elk River in 2015 and 2016 were significant; but in opposite directions, as noted above (Table 5.4; Figure 5.10).

Studies that examined zooplankton data collected from 1973 to 1988 reported that species composition was generally consistent among years (Hamilton et al. 1990; Richards 1997). The predominant genera of zooplankton collected were *Daphnia*, *Diaptomus*, and *Cyclops*. Total zooplankton biomass was considered low, consistent with an oligotrophic system

(Hamilton et al. 1990). Inverse correlations between *Cyclops* and *Diaptomus* densities, and *Daphnia* and *Bosmina* densities, were considered potentially indicative of a cyclic kokanee population and size-selective fish predation in Koocanusa Reservoir (Dalbey et al. 1998).

5.4.2 Tissue Selenium Concentrations

Selenium concentrations in zooplankton in Koocanusa Reservoir did not differ significantly between downstream and upstream areas in any of the three sampling years (Figure 5.11; Table 5.5). The BC interim guideline for invertebrates (4 µg/g dw), EVWQP Level 1 benchmarks for potential effects to benthic invertebrates (13 µg/g dw) and for dietary effects to juvenile fish (11 µg/g dw) are presented as a basis of comparison. Mean selenium concentrations measured in zooplankton were above the BC interim guideline for invertebrates in 2015 only, and were below the Level 1 benchmarks in all study years both upstream and downstream from the Elk River (Figure 5.11; Appendix Table G.1).

6 BENTHIC INVERTEBRATES

6.1 Overview

Benthic invertebrate community samples were collected in Koocanusa Reservoir in areas both upstream (T2/TN) and downstream (T4) from the Elk River in all three monitoring years (2014 to 2016) (Appendix Tables E.1 to E.16). Sampling occurred in August, when water levels are most stable (Figure 1.2) and benthic invertebrate communities are at or near maximum biomass and diversity (BCMOE 2006). Composite-taxa benthic invertebrate tissue samples were collected upstream (T2/TN) and downstream (T4) of the Elk River in both April and August for selenium and metals analysis.

6.2 Community Structure

Benthic invertebrate communities sampled in Koocanusa Reservoir upstream (T2/TN) and downstream (T4) of the Elk River were primarily composed of oligochaetes (mostly immature Tubificinae), insects (various species of chironomids), and ostracods in all three sample years (Figure 6.1; Appendix Tables E.1 to E.16). Total community density ranged from 984 to 3,533 organisms/m^2, which may be low compared to some reservoirs (e.g., Cowell and Hudson 1968), but brackets the value of 1,100 organisms/m^2 that Chisholm et al (1989) reported for samples collected in permanently wetted areas of Koocanusa Reservoir from 1983 to 1987.

Overall community density and richness did not differ significantly between upstream and downstream areas in any of the three study years (Table 6.1; Figure 6.2). However, community structure differed between areas, particularly with respect to ostracods, which were higher in density at the downstream area (range of 849 to 1,686 per m^2) compared to the upstream area (range of 38 to 333 per m^2) over the three years of study (Table 6.1). Absolute densities of oligochaetes were also significantly higher at the downstream area (range of 1,194 to 1,449 per m^2) compared to the upstream area (range of 418 to 1,194 per m^2; Table 6.1).

Beginning in 2015[11], ostracods were identified to species and *Cyntherissa lacustris* was found to be relatively abundant downstream and sparse upstream (Figure 6.3). *C. lacustris* is reputedly tolerant of a broad range in temperature (Danielopol et al. 1990; Külköylüoglu 2004), deep water (>40 m deep; Griffiths et al. 2002; Li et al. 2010), and DO concentrations as low as approximately 3 mg/L (Ruiz et al. 2013). The greater abundance of ostracods downstream of

[11] Ostracods were only identified to order in 2014 based on the guidelines for sampling benthic invertebrates in BC streams (BCMOE 2006); however, after recognizing that they represented a large proportion of the community, ostracods were identified to species in 2015 and 2016.

the Elk River compared to upstream may be associated with greater depths (Appendix Tables B.1 to B.3), and/or lower bottom water velocities, which are favorable for the development of these microcrustaceans (Ruiz et al. 2013). Also, portions of the upper reservoir dry out during low pool, and Curry (2003) reported fewer ostracods in lakes that went dry.

Overall benthic invertebrate community structure, as summarized by NMDS-Axis 1 scores (explaining 53% of variability in community structure between areas), differed significantly between the downstream and the upstream study area, with a similar magnitude of difference among years (i.e., 1.6 SD; Table 6.1; Appendix Tables E.17 to E.19). In particular, the downstream area had higher Axis 1 scores in all three years with the difference mainly associated with a greater density of ostracods, and *Heterotrissocladius* and *Tanytarsus* midges (Figure 6.4), as identified in Table 6.1.

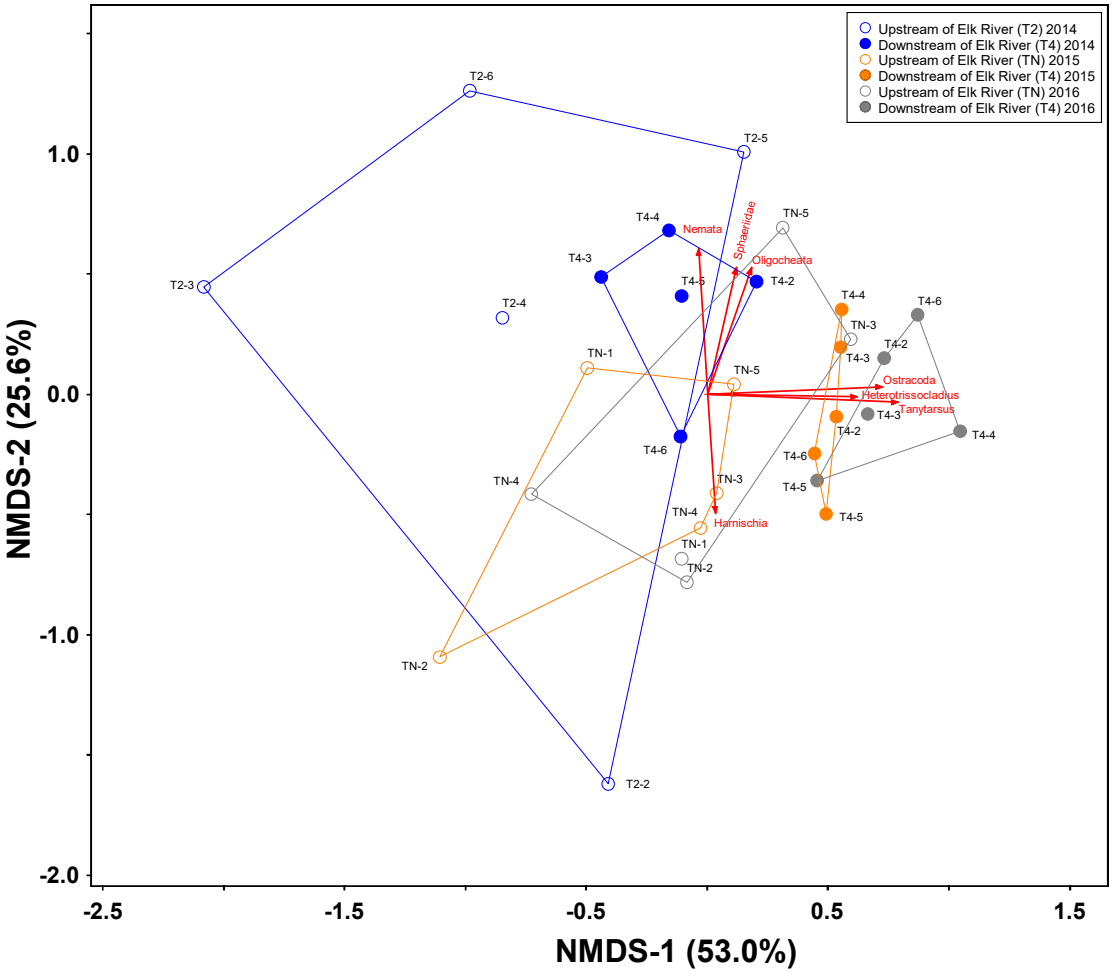

Figure 6.4: Benthic Invertebrate Community Structure (Lowest Practical Level of Taxonomy) in Koocanusa Reservoir as Summarized by NMDS, 2014 to 2016

6.3 Tissue Selenium Concentrations

Composite-taxa benthic invertebrate tissue samples collected in April and August consisted mainly of chironomids with some oligochaetes. Low densities resulted in very little tissue mass relative to the amount of area sampled at each location and time period (e.g., about 0.4 g wet weight in April 2015 from a total of 20 Petite Ponar grabs; Appendix Table G.1). Consequently, only a single tissue sample was obtained per area during each sampling event.

Benthic invertebrate selenium concentrations were 29% greater, on average, at the downstream area compared to the upstream area over the three years of study (Table 6.2). The difference in tissue concentrations between areas did not increase after the upstream station was moved farther upstream in early 2015, suggesting limited influence from the Elk River on tissue chemistry at the upstream station in 2014. Selenium concentrations at the downstream area ranged from 5.3 to 9.7 µg/g dw, compared to 2.0 to 7.8 µg/g dw at the upstream area over the three years of study (Figure 6.5; Appendix Table G.1;). Eleven of 12 samples collected between the two areas had tissue selenium concentrations above the interim BCMOE guideline of 4 µg/g dw (except the August sample for the upstream area in 2015). Concentrations in all samples were less than the EVWQP Level 1 benchmarks for potential effects to invertebrates (13 µg/g dw) and for dietary effects to fish (11 µg/g dw) (Figure 6.5).

Table 6.2: Statistical Summary of Spatial and Temporal Differences in Benthic Invertebrate Tissue Selenium Concentrations in Koocanusa Reservoir, 2014 to 2016

' * ' indicates the downstream area was significantly different from the upstream area in the same year.

7 FISH

7.1 Overview

Fish were sampled in the Canadian portion of the Koocanusa Reservoir to evaluate endpoints indicative of individual and population health as well as tissue chemistry. Three areas were sampled in the reservoir, two downstream from the Elk River (Elk River and Gold Creek), and one upstream from the Elk River (Sand Creek) (Figure 2.2).

For the fish health surveys, peamouth chub were targeted in April of the first year of study (Minnow 2014b). Additional species were targeted in 2015 and/or 2016 based on ease of capture using the sampling gear permitted under the provincially issued scientific collection permit, and reproductive maturity observed during April sampling (northern pikeminnow, redside shiner, yellow perch, largescale sucker) (Minnow 2015c, 2016b). Endpoints associated with fish survival (mean age), growth (body size-at-age), reproduction (relative gonad weight) and energy storage (relative liver weight and overall condition) were statistically compared between the downstream areas and the upstream area. Magnitudes of difference were interpreted relative to commonly accepted Critical Effect Sizes (CES; Munkittrick et al. 2009; Environment Canada 2012).

Tissues were collected for analysis of selenium and mercury from species sampled for the fish health surveys (April each year), and from other species, including sport fish (February, April, August). Tissue concentrations were statistically compared between the downstream areas and the upstream area and were also compared to available provincial guidelines (BCMOE 2017a), US EPA criteria (USEPA 2016), and Level 1 benchmarks developed in the EVWQP (Teck 2014). Although a formal fish community evaluation was not an objective of the fish survey, the abundances of different species captured were summarized to provide indication of the fish community composition. Based on cultural importance to the Ktunaxa First Nation, a separate study of burbot was completed in 2014 to 2015 (Minnow 2015a) and results are also summarized in this report.

7.2 Fish Community

7.2.1 Previous Studies

Prior to construction of the Libby Dam, the sportfish fishery in the Kootenay River (which was later impounded to form the reservoir) consisted primarily of westslope cutthroat trout, rainbow trout, mountain whitefish, and burbot (Hamilton et al. 1990). Shortly following impoundment, an increase in nutrients due to the inundation of substrates was hypothesized to account for a substantial increase in total fish biomass, including several native species such as westslope

cutthroat and rainbow trout, mountain whitefish, peamouth chub, northern pikeminnow, and sucker species (Hamilton et al. 1990; Richards 1997). Among game species, westslope cutthroat trout, bull trout, mountain whitefish, and burbot were initially most common, whereas longnose sucker and invasive yellow perch were initially the most common non-cyprinid, non-game species (Richards 1997). Kokanee were released into the reservoir from the Kootenay Trout Hatchery in BC in 1979, and yellow perch may have inadvertently colonized the reservoir through emigration from Murphy Lake in Montana (Huston et al. 1984; Hamilton et al. 1990).

Following the initial increase in total fish biomass within the reservoir, numbers of native westslope cutthroat trout and rainbow trout (i.e., *Oncorhynchus* spp.) declined, while kokanee numbers increased, potentially as a result of competition for available food, changes in available spawning and rearing habitat due to deep drawdown levels and flushing of nutrients from the reservoir (Dalbey et al. 1998). The numbers of native *Oncorhynchus* spp. captured in gill nets declined independent of number and size of hatchery fish stocked into the reservoir over time. Mountain whitefish and redside shiners captured in gill nets showed similar declining trends as shown for the *Oncorhynchus* spp., which was hypothesized to reflect a loss of spawning and rearing habitat, and competition with kokanee for plankton food resources (Dalbey et al. 1998).

7.2.2 Koocanusa Reservoir 2014 – 2016

Fish communities at the Sand Creek, Elk River, and Gold Creek study areas in 2014 to 2016 were represented by a total of 14, 12, and 13 species, respectively (Table 7.1). Largescale sucker, northern pikeminnow, peamouth chub, redside shiner, and yellow perch were consistently captured in highest numbers at all three study areas (Table 7.1). Variability in the diversity and abundance of fish captured among years was likely due to annual differences in collection gear and sampling effort (i.e., angling, burbot trapping, gill netting, hoop netting, minnow trapping and/or seine netting; Appendix Tables F.1 to F.44).

7.2.3 Burbot

Burbot are one of the few Canadian freshwater fish species that spawn in midwinter (Scott and Crossman 1998). In Canada, burbot spawning typically occurs under-ice from January to March in nearshore waters or shallow offshore shoals at depths of approximately 1 – 3 m (Ford et al. 1995; Scott and Crossman 1998; Spence 1999). Preferred spawning locations in lakes appear to be associated with tributary confluences or groundwater upwelling (Ford et al. 1995; Spence and Neufeld 2002). Burbot eggs hatch in about 30 days (at 6 °C), and larvae typically appear in late February to June (Scott and Crossman 1998). Once the eggs hatch, larvae spend several days resting on the bottom before becoming free-swimming and planktonic. Young-of-the-year burbot are frequently found in rocky shorelines and sometimes in

[d] Fish captured in 2016 by angling, gill netting, and/or hoop netting.

weedy areas of tributary streams (Scott and Crossman 1998). In contrast, adult burbot prefer deeper water and, after spawning, move to hypolimnic habitat (Scott and Crossman 1998). Burbot are voracious predators that commonly feed at night. Young burbot (<500 mm in length) feed mainly on aquatic insects, while burbot over 500 mm in length feed almost exclusively on fish, including kokanee, peamouth chub and northern pikeminnow, among others (Scott and Crossman 1998).

Historically, burbot supported a productive fishery in the lakes and streams of southeastern Kootenay region (Prince 2007). In recent years, however, the lower Kootenay burbot populations were designated as critically imperiled and red-listed, meaning potentially extirpated, endangered, or threatened (BCMOE 2015). Gill netting surveys completed by Montana Fish, Wildlife and Parks in the lower Koocanusa Reservoir, beginning in 1975, indicated that the relative abundance of burbot increased until the late 1980s, followed by continual decline to current low levels (Dunnigan 2015).

Limited information exists regarding the life history and spawning distribution of burbot within Koocanusa Reservoir (Dunnigan and Sinclair 2008). Recent investigation of the movement patterns of burbot in Koocanusa Reservoir suggested that burbot exhibited pre-spawning migratory behavior, with movement up to 64.3 km in a season, but movement was more limited in other seasons, similar to studies in other areas (Paragamian and Wakkinen 2008, Gardner and Stewart 1987). Burbot in the Koocanusa Reservoir demonstrated strong fidelity to a particular side, implying limited mixing of fish from opposite shorelines (Dunnigan and Sinclair 2008). In addition, burbot showed affinity for the former Kootenay River channel within the reservoir, presumably because it is the deepest and coolest portion of the reservoir. Overall, the mean 50%, 75%, and 90% home range sizes for burbot in the reservoir were estimated to be 14.6, 22.6, and 32.3 km^2, respectively, which is substantially larger than most fish species in lake environments (Minns 1995; Dunnigan and Sinclair 2008). Minns (1995) speculated that aside from ecological differences between species, fish residing in larger habitats with lower productivity would require larger home ranges to obtain food. In Koocanusa Reservoir, kokanee are a key prey item for burbot, and their pelagic and transient nature could in part explain the larger home range (Dunnigan and Sinclair 2008).

Based on concerns about burbot abundance, and the cultural importance of this fish species to the Ktunaxa First Nation, a study of burbot tissue selenium concentrations was undertaken in 2014 and 2015 (Minnow 2015a). The objective was to measure tissue selenium concentrations in pre-spawning females, if possible. Conditions in the fish collection permit required that samples be taken non-lethally (i.e., expressed eggs, if ripe females were caught, and muscle plugs). However, the combined catch of burbot in February of 2014 and 2015 totaled eight

individuals, despite considerable effort (i.e., 148 angling hours and 122.6 hoop net days; Appendix Tables F.1, F.4, F.8 and F.13). Although burbot were not targeted in 2016, any individuals caught opportunistically were also sampled non-lethally for tissue selenium analysis in 2016. In total, 43 burbot were captured among the three study areas in Koocanusa Reservoir from 2014 to 2016 (Table 7.1; Figure 7.1) with the majority (31 burbot) collected through hoop netting[12] in the April field programs (Appendix Tables F.37 to F.44). The tissue selenium concentrations are presented and discussed in Section 7.4.

The suspected link between burbot productivity and reservoir operations has also made burbot a species of concern elsewhere, such as the Kinbasket Reservoir on the Columbia River (Warnock et al. 2014; Kang et al. 2015). Winter drawdown of the Kinbasket Reservoir (impounded by the Mica Dam in 1973) causes water elevations to vary typically by about 35 m, similar to Koocanusa Reservoir. This exposes large areas of littoral habitat which is suspected to cause dewatering of burbot eggs and/or larvae, with commensurate reduction of recruitment (Warnock et al 2014). A study was initiated by the Canadian Columbia River Inter-Tribal Fisheries Commission (CCRIFC) involving capture and surgical implantation of burbot in Kinbasket Reservoir with acoustic-radio transmitters to determine shallow reservoir and tributary habitat use during the spawning season (Warnock et al 2014). Given the comparable fluctuations in water elevations between the two reservoirs, it is possible similar effects could be expected on burbot in Koocanusa Reservoir.

7.3 Fish Health and Population Assessment

7.3.1 Largescale Sucker

7.3.1.1 General Biology

Largescale suckers spawn in the spring over a variety of substrate types at lake inlets and outlets (McEvoy 1998). Although some individuals may migrate in excess of 100 km during the spawning period and return to within 0.2 km of their original home range following spawning, other individuals may not migrate far to spawn (McEvoy 1998). Largescale sucker eggs typically hatch within 14 days and fry generally remain closely associated with the substrate for the first few weeks until the yolk sac is absorbed and the mouth becomes terminal, at which point they become pelagic (Scott and Crossman 1998). Growth of fry is slow, and as fish grow larger, fry move toward the bottom and into deeper water. Adult largescale sucker inhabit large rivers and lakes, and are usually found at a depth of a few meters in weedy shore areas of

[12] Hoop netting with a lead could not be effectively used in February because the reservoir was frozen (as in 2014) or there were ice flows that entangled gear (as in 2015).

lakes, in backwaters, and at stream mouths (Scott and Crossman 1998). Outside of spawning migration, largescale suckers do not move significantly during the summer, fall, or winter, and in river environments, often reside within one pool-riffle sequence with net upstream-downstream movement limited to 200 to 300 m (McEvoy 1998). Adult largescale sucker feed almost exclusively on benthic-dwelling invertebrates, including ostracods, copepods, amphipods, Trichoptera (caddisflies), Chironomidae (midges) and molluscs (Scott and Crossman 1998). Following the spawning of various salmonids, largescale sucker are also known to feed on fish eggs deposited on bottom substrates (Scott and Crossman 1998).

7.3.1.2 Health Assessment

The largescale sucker health assessment was only conducted on females collected in 2015 and 2016 and males in 2016 (i.e., sample size for males in 2015 was too small [n = 1, 5, and 5 for Sand Creek, Elk River, and Gold Creek, respectively; Appendix Table F.23 and Figures F.1, F.2, and F.11]). Male and female largescale sucker captured among the three study areas ranged in age from 7 to 18 years (Figure 7.2 and 7.3). Mean age of female and male largescale sucker did not differ significantly between study areas located downstream versus upstream of the Elk River (Table 7.2). In addition, there were no consistent downstream to upstream differences between years or sexes for endpoints indicative of largescale sucker growth (size relative to age), energy storage (body weight relative to length, liver weight relative to body weight), or reproduction (gonad size relative to body size) (Table 7.3). Males sampled at both downstream areas in 2016 showed a similar pattern of reduced condition among small individuals and increased condition among larger individuals; but the magnitudes of difference at the Elk River area were less than the CES of 10%, and smaller than observed at the Gold Creek area. Internal body cavity tapeworms were the most common abnormality observed in all fish species during the fish health assessment (Table 7.4; Appendix Tables F.45 to F.47). No tapeworms were observed in largescale suckers captured at the Elk River study area, whereas approximately 8% and 3% of largescale suckers from the Gold Creek and Sand Creek study areas, respectively contained tapeworms (Table 7.4; Appendix Tables F.23 and F.24).

7.3.2 Northern Pikeminnow

7.3.2.1 General Biology

Northern pikeminnow spawn from late May to early August, often congregating in large numbers to spawn on gravelly lake shallows either along the shoreline or near a tributary (Scott and Crossman 1998; Gadomski et al. 2001; Gray and Dauble 2001). They reach maturity between 4 (males) and 5 (females) years (around a 300 mm length), and exhibit multiple spawning episodes within the spawning season (Scott and Crossman 1998). Eggs hatch in approximately

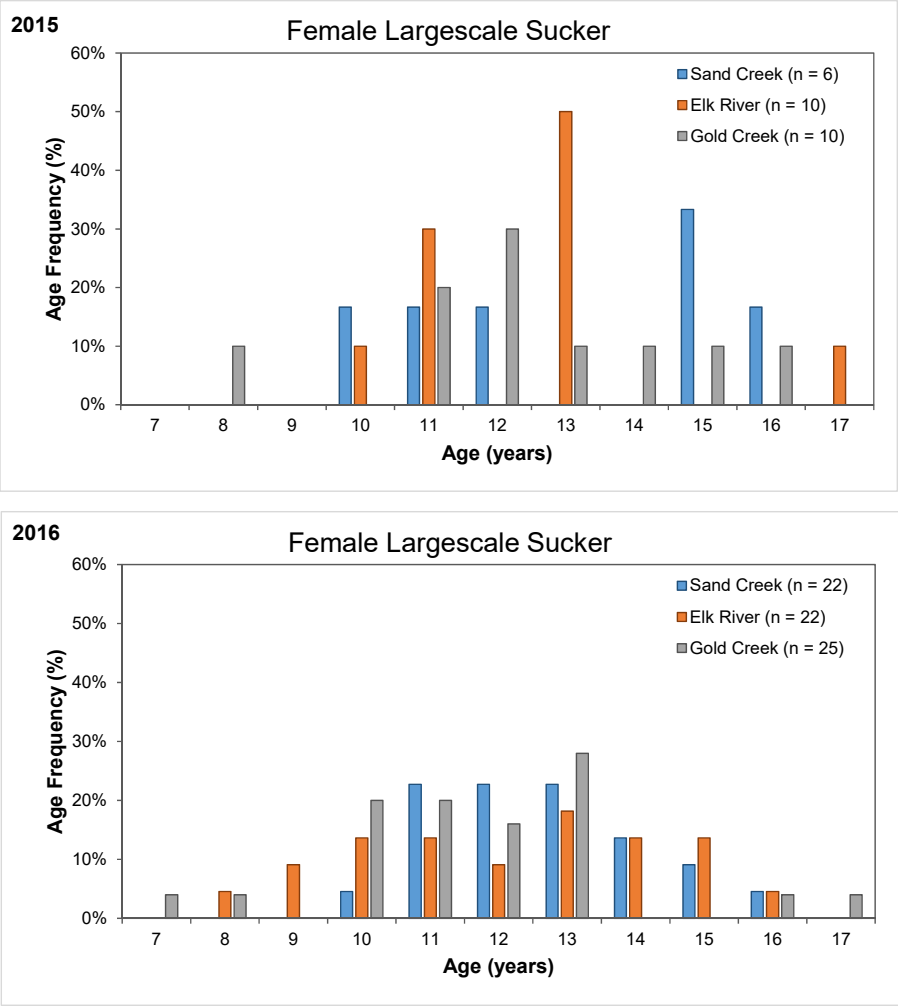

Figure 7.2: Relative Age Distribution of Female Largescale Sucker in Koocanusa Reservoir, April 2015, and 2016

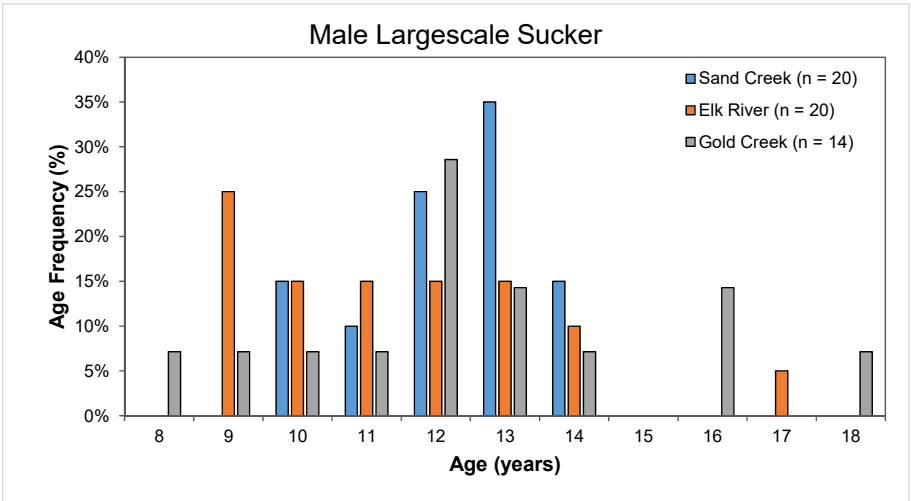

Figure 7.3: Relative Age Distribution of Male Largescale Sucker in Koocanusa Reservoir, April 2016

7 days, with the young fish generally remaining inshore in the summer and moving offshore in the fall and winter. Larger individuals reside predominately in lakes and tend to remain offshore (Gray and Dauble 2001; Scott and Crossman 1998). Northern pikeminnow feed predominately on small fish (shiners, stickleback), terrestrial insects and plankton in the summer, and during fall and winter diet generally shifts to fish in the offshore areas (Scott and Crossman 1998). In Koocanusa Reservoir, northern pikeminnow appear to be opportunistic feeders, consuming a variety of organisms, but primarily relying upon fish (Lotic 2017). Seven different species of fish were consumed by northern pikeminnow in the reservoir, with kokanee and peamouth chub being most common (Lotic 2017).

7.3.2.2 Health Assessment

Female northern pikeminnow captured in Koocanusa Reservoir ranged in age from 5 to 22 years and male northern pikeminnow generally ranged in age from 6 to 16 years (with two individuals documented at 25 and 26 years of age[13]; Figures 7.4 and 7.5; Appendix Figures F.3, F.4, F.12, and F.13 and Table F.26). The large range in northern pikeminnow ages likely reflected the wide variety of fish collection methods used between the two years. No differences were observed between the downstream and upstream areas that would be indicative of influence from the Elk River (Tables 7.2 and 7.3). For example, most significant differences were associated with pikeminnow collected at the Gold Creek area compared to Sand Creek. Very few abnormalities were observed in northern pikeminnow, and no tapeworms were observed in any individuals collected in 2015 (Appendix Tables F.45 to F.47). Only 2%, 3% and 8% of individuals collected at the Elk River, Gold Creek and Sand Creek study areas, respectively, had tapeworms in 2016 (Table 7.4).

7.3.3 Peamouth Chub

7.3.3.1 General Biology

Peamouth chub spawn in large groups in late spring in the shallow shoreline habitat of lakes (Scott and Crossman 1998). Newly hatched young remain in schools along the shore and move into deeper water in late summer. Generally, peamouth chub inhabit the weedy shallows of lakes and rivers for most of the year where they tend to form schools (Scott and Crossman 1998), although adults appear to move offshore by mid-summer (Gray and Dauble 2001). Peamouth chub are mainly insectivorous, feeding on a wide variety of aquatic insects

[13]Confidence around ages (using otoliths) decreased beyond 17-19 years (zones) and ages provided are best estimates (Appendix H).

[b] Includes fish caught from the Englishman Creek sampling location in February 2014.

and larvae as well as terrestrial insects (Scott and Crossman 1998). In Koocanusa Reservoir, peamouth chub fed mainly on aquatic insects (i.e. Diptera larvae and pupae) and zooplankton (e.g., *Daphnia* spp.), with terrestrial insects constituting a smaller, but important, portion of prey items (Lotic 2017).

7.3.3.2 Health Assessment

Female peamouth chub ranged in age from 3 to 27 years, whereas males ranged from 3 to 14 years over the 2014 to 2016 sampling program (Figures 7.6 and 7.7; Appendix Figures F.5, F.6, F.14, and F.15 and Table F.28). There were no differences in mean age (Table 7.2) or differences among the other endpoints (Table 7.3) that could be considered indicative of influence from the Elk River. For example, lower condition among females (3.2%) and males (4.4%) captured at Gold Creek compared to Sand Creek was not observed at the Elk River sampling area compared to Sand Creek. Peamouth chub showed a relatively high incidence of tapeworms at all study areas, ranging from 2% to 38% of individuals within a study area from 2014 to 2016 (Table 7.4). Peamouth chub gonad development appeared to be inhibited by the presence of tapeworms, which is consistent with typical responses of cyprinids shown in the literature (Carter et al. 2005).

7.3.4 Redside Shiner

7.3.4.1 General Biology

Redside shiners generally spawn between May and July in groups of 30 to 40 fish, both in streams and in lakes when water temperatures reach approximately 10°C, and show a strong affinity for natal spawning grounds (Scott and Crossman 1998). Eggs tend to hatch 3 to 15 days post-spawning, depending on water temperature. Redside shiners usually reach sexual maturity by their third year. They occur in schools of thousands in large lakes, ponds, and moderately fast-moving streams, tolerating a wide variety of temperatures and trophic conditions. In lakes, smaller individuals tend to remain in the upper water column and/or close to shore. Other than during spawning migration, redside shiners exhibit very little directed movement aside from movements on and off shoals in lake environments related to changes in water temperature (Scott and Crossman 1998). Redside shiner fry feed mainly on plankton and demersal crustaceans while larger fish are mainly insectivorous, but feed on fish eggs opportunistically. Egg predation by redside shiners can have large influences on trout populations in cases where accidental releases have occurred to lakes previously utilized solely by trout (Scott and Crossman 1998).

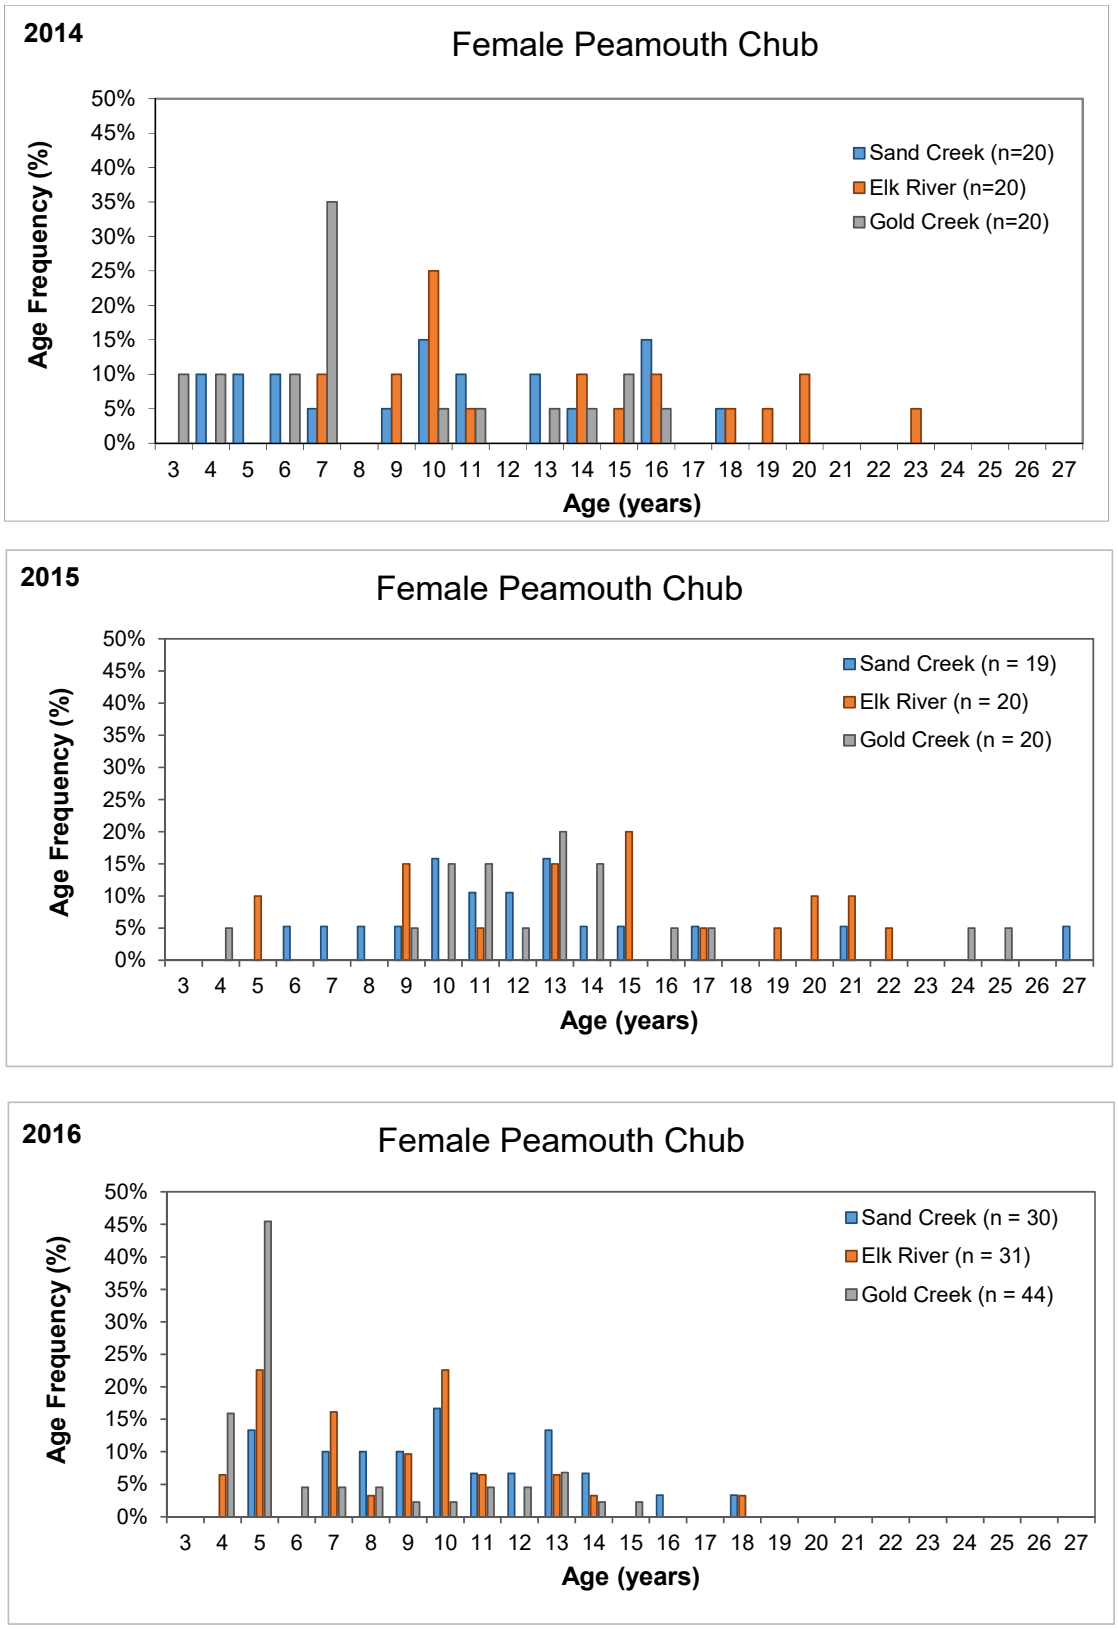

Figure 7.6: Relative Age Distribution of Female Peamouth Chub in Koocanusa Reservoir, 2014 to 2016

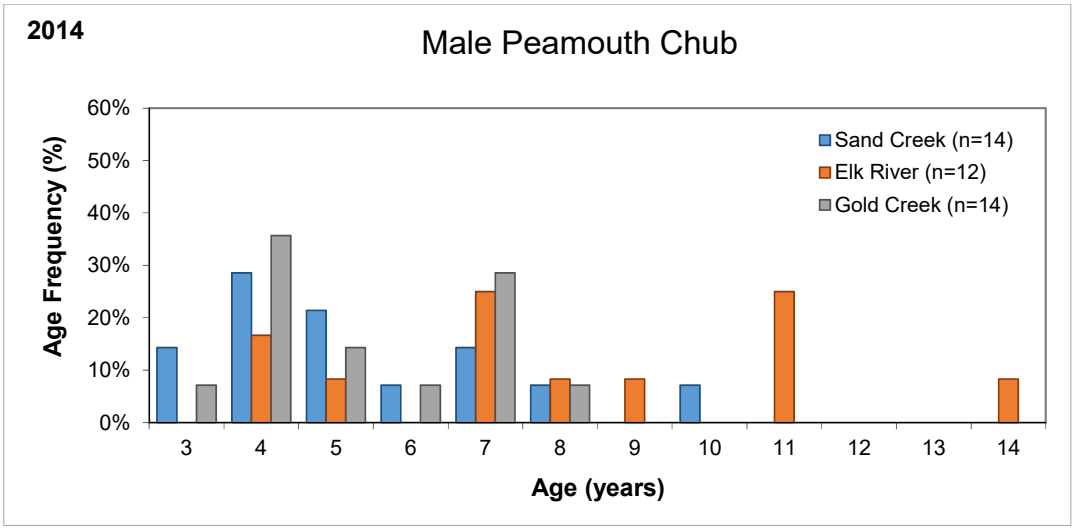

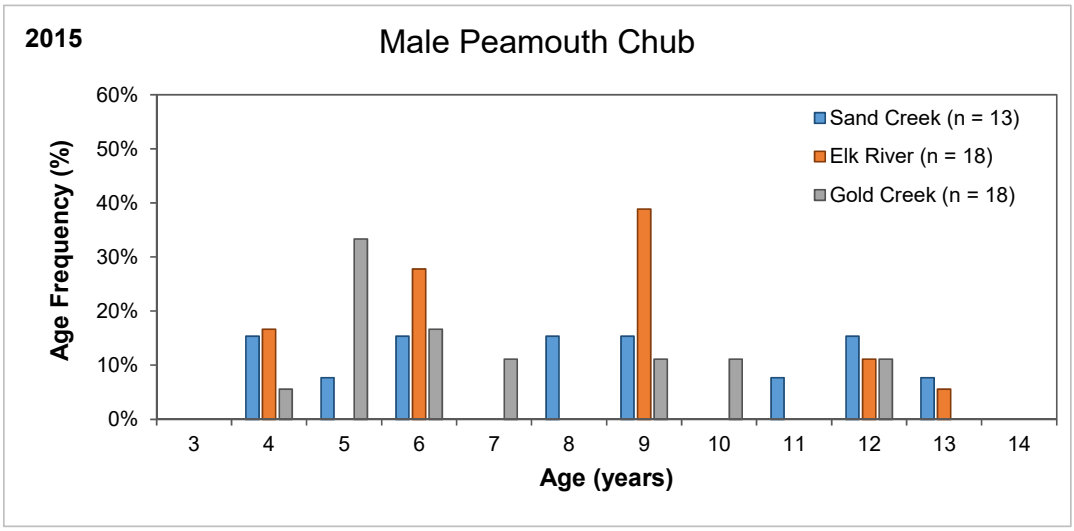

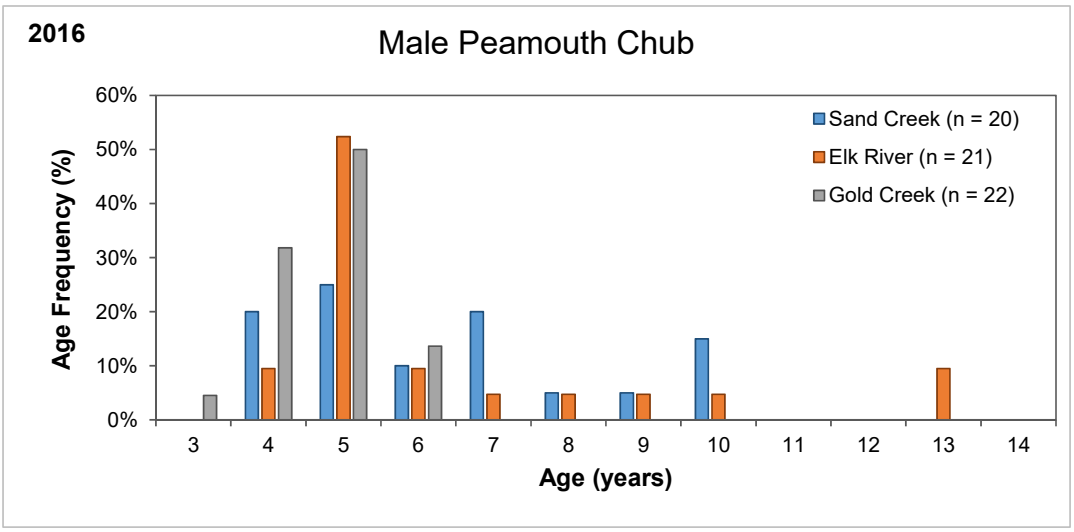

Figure 7.7: Relative Age Distribution of Male Peamouth Chub in Koocanusa Reservoir, 2014 to 2016

7.3.4.2 Health Assessment

Redside shiner health were only assessed in 2016 due to limited sample sizes of fish with sufficient gonad development to determine sex in 2015 (Appendix Table F.31 and Figures F.7 and F.8). Overall catch yields were greater in 2016 when gill nets were permitted for use (Appendix Tables F.40 to F.44), but a large proportion of individuals in both years had unripe gonads (Appendix Table F.31). Lack of gonad development may have been related to the high proportion (21 to 60%) of tapeworms infections in this species, particularly at the downstream areas (42 to 60%; Table 7.4). The tapeworm *Ligula intestinalis* has been shown to inhibit gonad development in various cyprinid species (Carter et al. 2005). Female redside shiners ranged in age from 3 to 5 years, whereas males ranged from 2 to 4 years in 2016 (Figure 7.8). Liver sizes of female redside shiner were greater at both downstream areas than at Sand Creek, but males showed a difference in liver size only at the Gold Creek area (Table 7.3). Other than greater liver weight at the Gold Creek area compared to Sand Creek, no other differences in endpoints were observed for redside shiner between the downstream and upstream areas in 2016.

7.3.5 Yellow Perch

7.3.5.1 General Biology

As a result of their commercial and recreational importance, a considerable amount of information is available regarding various aspects of the life history of the yellow perch (Scott and Crossman 1998). In lakes and large rivers, adult yellow perch migrate towards the shore, or into tributaries, to spawn. Spawning usually takes place at night and early morning, often near or on rooted vegetation and/or woody debris. Eggs usually hatch within 8 to 10 days of spawning, and juveniles grow relatively rapidly, with sexual maturity usually reached by age 3 in males and age 4 in females (Scott and Crossman 1998). Yellow perch exploit a wide variety of warm to cool water habitats from large lakes to ponds and quiet rivers, although they are typically most abundant in the open waters of lakes. Young-of-the-year yellow perch are often seen in large compact schools, while adults are often found moving in a loose aggregation of 50 to 500 individuals. They are considered shallow water fish, not typically found below 9 m, but exhibit a seasonal vertical movement in order to maintain a roughly 20°C isotherm (Scott and Crossman 1998). Studies in the Great Lakes have suggested that during the summer months, yellow perch movement is relatively limited, but that during cooler months, greater distances may be travelled (Glover et al. 2008). Although some studies suggest that yellow perch may travel from 13 km to over 100 km through the year, tagging studies generally indicate a high degree of site fidelity and most often travel is limited to the lower end of this range (Glover et al. 2008). Minns (1995) characterized the home range size for yellow perch to be

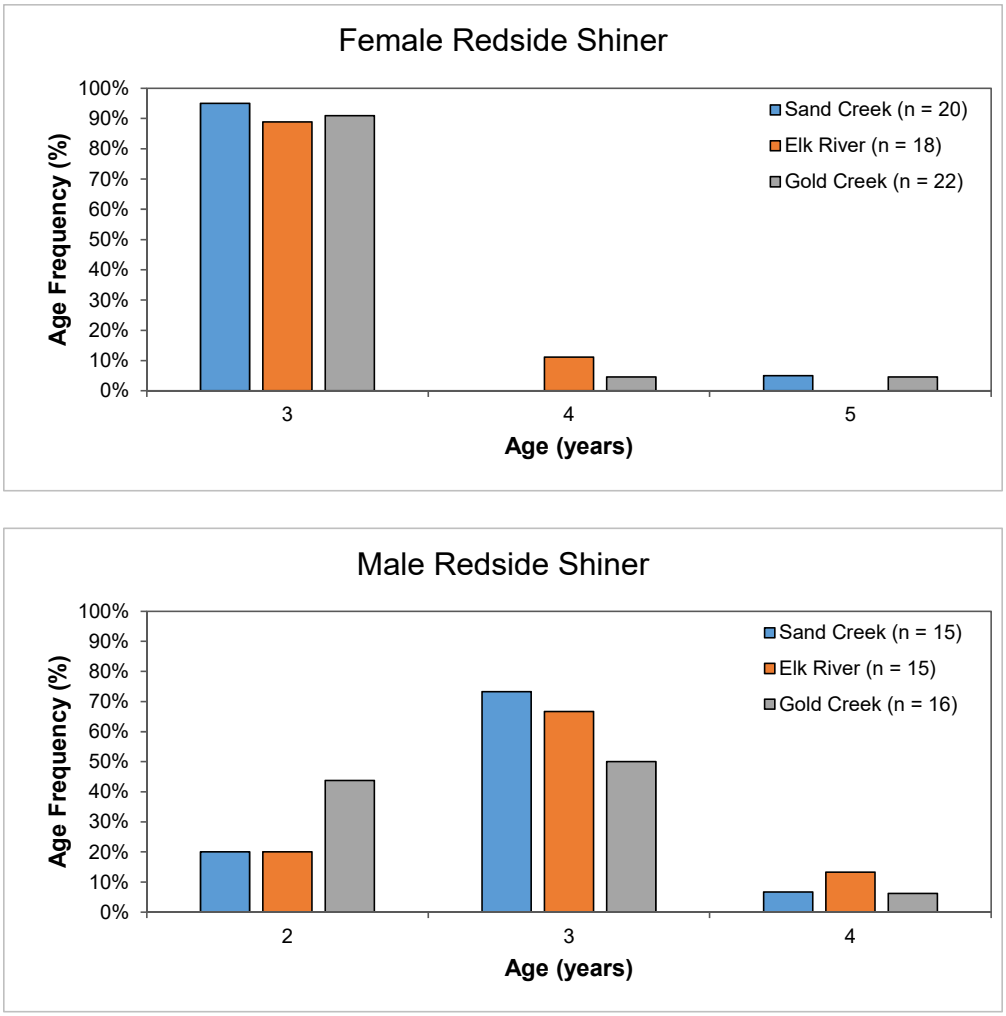

Figure 7.8: Relative Age Distribution of Male and Female Redside Shiner in Koocanusa Reservoir, April 2016

relatively small, from approximately 0.007 to 0.011 km^2. The diet of yellow perch largely consists of immature insects, larger invertebrates, and fishes taken from both the open water and the substrate. In Koocanusa Reservoir, yellow perch relied heavily on aquatic insects (mainly Diptera spp. larvae) with redside shiner comprising the remainder of the diet, although the sample size supporting these observations was small (six; Lotic 2017).

7.3.5.2 Health Assessment

Female and male yellow perch ranged from 2 to 8 years of age in 2015 and 2016 (Figures 7.9 and 7.10; Appendix Figures F.9, F.10, F.16, and F.17 and Table F.35). No consistent significant differences were found between the downstream study areas and the Sand Creek study area to indicate influence from the Elk River (Tables 7.2 and 7.3). Yellow perch abnormalities, including

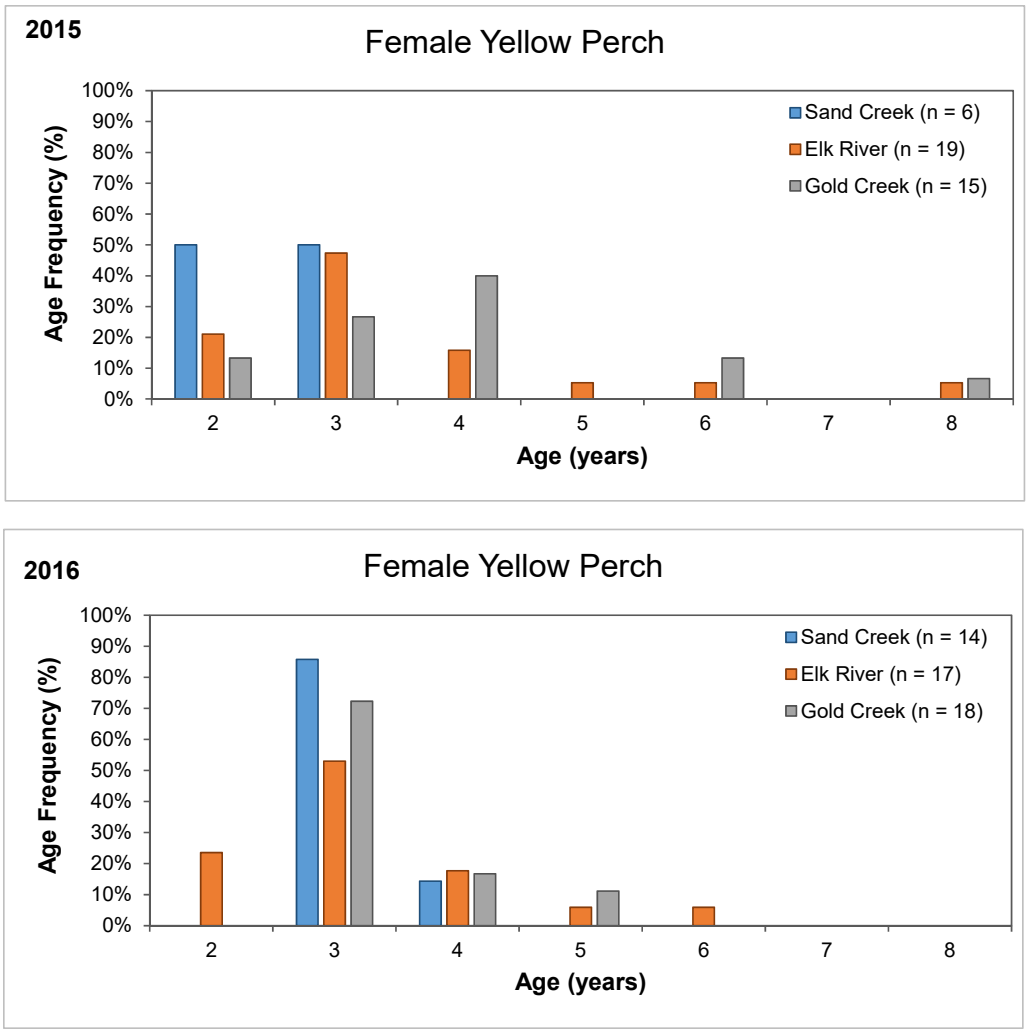

Figure 7.9: Relative Age Distribution of Female Yellow Perch in Koocanusa Reservoir, April 2015 and 2016

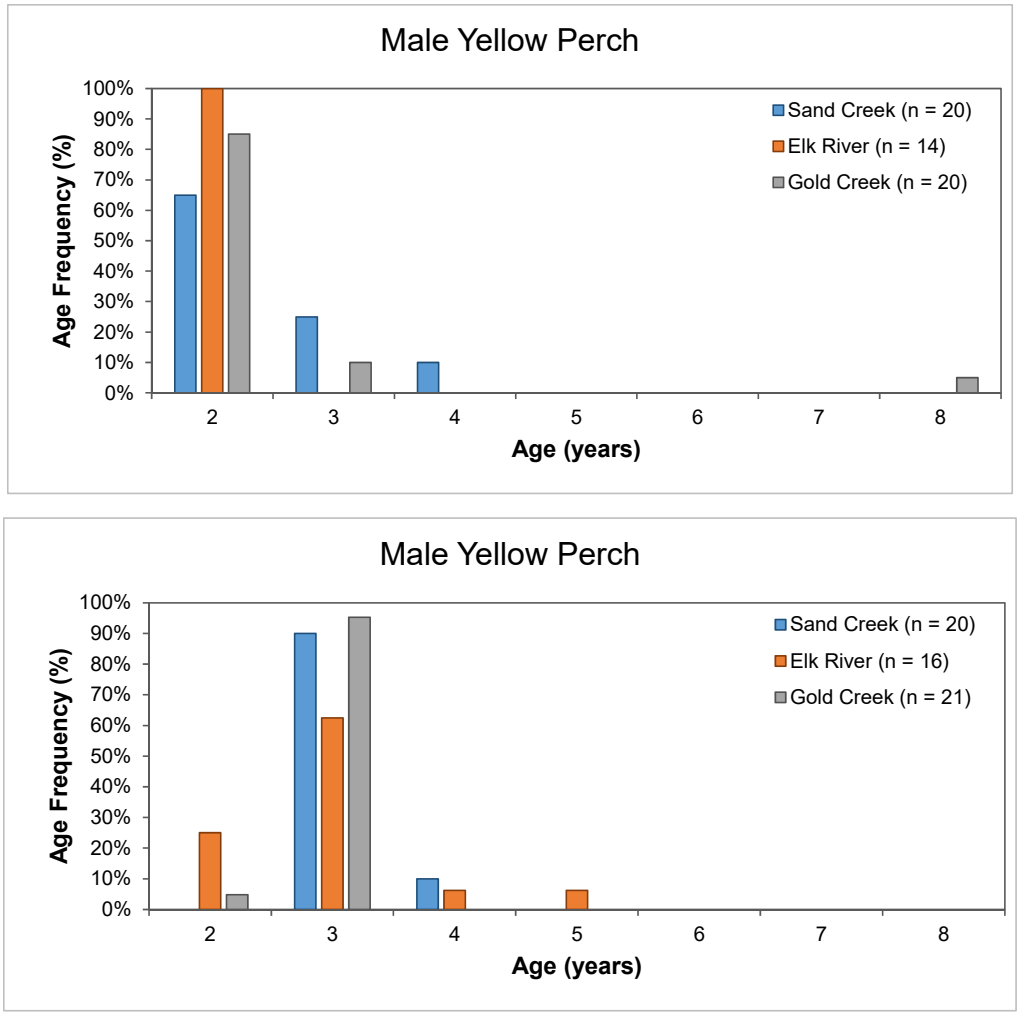

Figure 7.10: Relative Age Distribution of Male Yellow Perch in Koocanusa Reservoir, April 2015 and 2016

the incidence of internal tapeworms, were comparable among all three study areas in 2015 (i.e., ≤ 3%), but were more prevalent at the Elk River and Gold Creek study areas (20% and 7% of total individuals, respectively) in 2016 (Table 7.4 and Appendix Tables F.45 to F.47).

7.4 Tissue Selenium Concentrations

7.4.1 Muscle

Muscle selenium concentrations in largescale sucker, peamouth chub, yellow perch, and redside shiner from the Elk River downstream area were consistently greater than those in fish from the upstream Sand Creek area (Table 7.5; Appendix Figures F.18 to F.28). Selenium concentrations in northern pikeminnow muscle were also greater at the Elk River area compared to Sand Creek in 2014 and 2015, but were lower than at Sand Creek in 2016

Table 7.5: **Statistical Summary of Spatial and Temporal Differences in Fish Tissue Selenium Concentrations at the Downstream Areas (Elk River and Gold Creek) Compared to the Upstream Area (Sand Creek) in Koocanusa Reservoir using a Two-way ANOVA (at Least Two Years of Data) or ANOVA/Kruskal-Wallis Test (One Year of Data), 2014, 2015 and/or 2016**

p-value < 0.1.

* indicates a significant difference between the two areas at an α of 0.1.

[a] The measure of central tendency reported is based on the applied data-transformation, as follows: mean for no transformation; geometric mean for $\log_{10}$-transformation; and, median for rank-transformation.

NA indicates not applicable as no data were collected for this species in the given year.

(Table 7.5). Selenium concentrations in the muscle of peamouth chub (all study years) and yellow perch (2016 only) from the Gold Creek study area were also higher than those from Sand Creek (Table 7.5).

Fish muscle selenium concentrations were below the USEPA (2016) criteria of 11.3 µg/g dw at all study areas, with the exception of one yellow perch collected at the Elk River downstream study area in April 2015 (Figure 7.11). Four of the eleven species sampled (largescale sucker, mountain whitefish, northern pikeminnow, and yellow perch) had mean muscle selenium concentrations greater than the BCMOE guideline (4 µg/g dw) at the downstream Elk River area (Figure 7.11). The single burbot and westslope cutthroat trout collected from the Elk River area in April 2015 and 2016, respectively, also had muscle selenium concentrations above the BCMOE guideline. The mean selenium concentration in mountain whitefish muscle was also above the BCMOE guideline at the upstream Sand Creek area (Figure 7.11). However, it should be noted that these comparisons of individual fish to the BCMOE guideline are potentially misleading, as the BCMOE guidelines for tissue concentrations are intended to be compared to the mean of at least 8 fish. As further data becomes available from future monitoring programs, muscle selenium concentrations comparisons to the BCMOE guidelines will be updated.

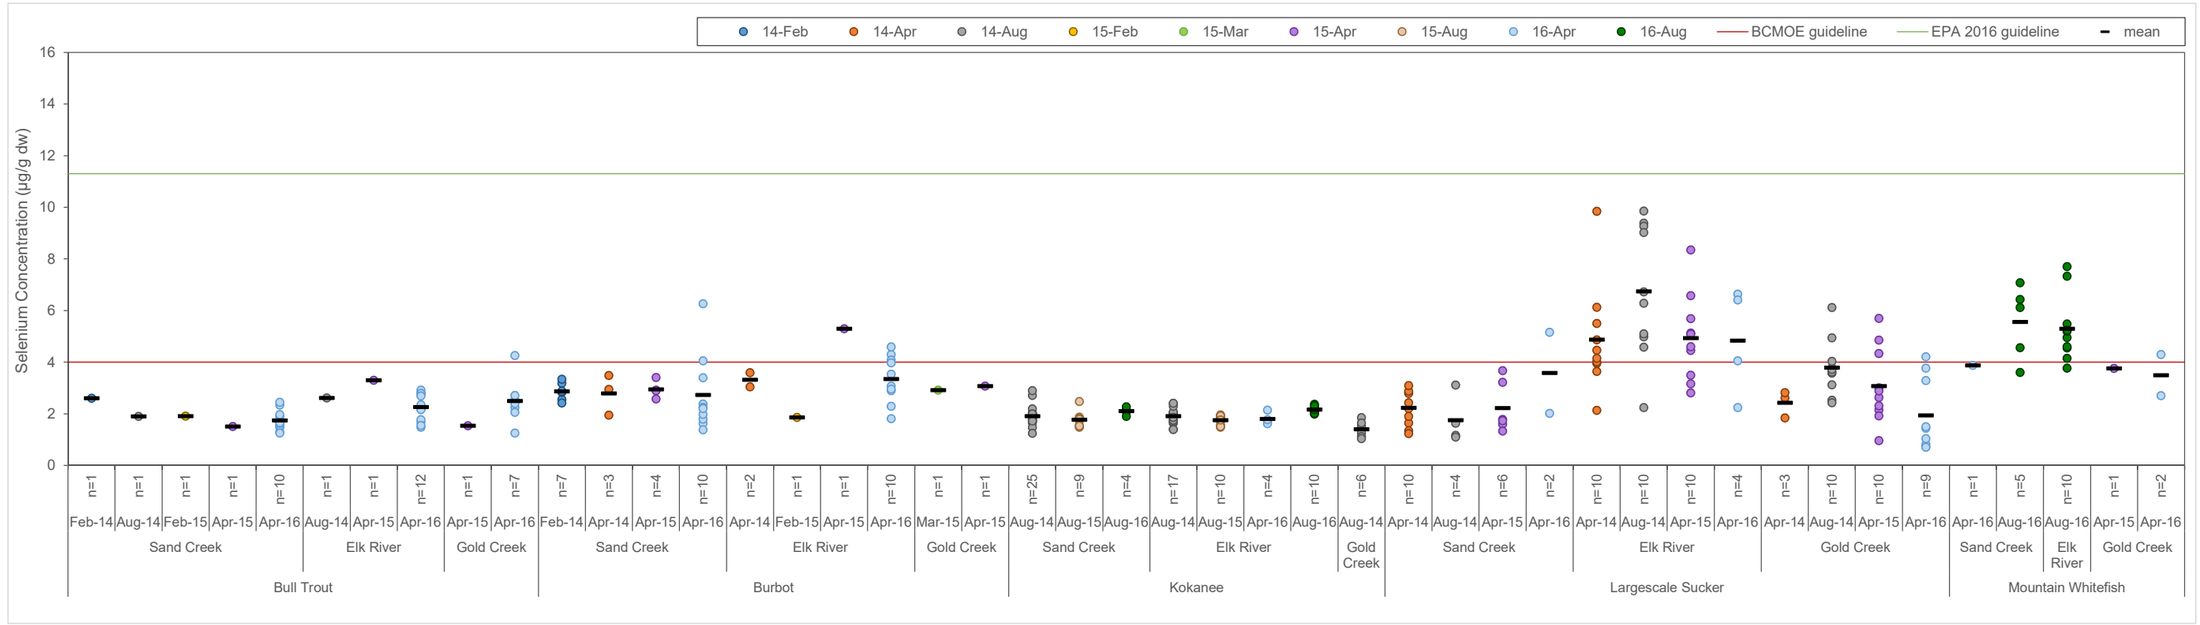
A temporal comparison (April versus August) of selenium concentrations in muscle of northern pikeminnow was completed using three-way ANOVA. There were no significant interactions between Month and Area or between Month and Year indicating that differences in selenium concentrations between months (April and August) did not depend on area (Sand Creek, Elk River, and Gold Creek) or year (2014 to 2016). Differences between months could therefore be evaluated after combining data among years and areas for each month. The mean muscle selenium concentration in northern pikeminnow was significantly greater (7.7%) in August compared to April (Figure 7.12).

7.4.2 Whole Body

No differences were found between whole body peamouth chub selenium concentrations from the downstream areas (Elk River and Gold Creek) relative to the upstream area (Sand Creek; Table 7.5). All whole body selenium concentrations for peamouth chub and redside shiner were less than the USEPA (2016) criteria of 8.5 µg/g dw and mean values were at or below the BCMOE guideline of 4 µg/g dw in all study areas in all three years (Figure 7.13).

7.4.3 Ovary

In contrast to results for muscle selenium concentrations which typically indicated higher concentrations downstream compared to upstream from the Elk River, yellow perch was the



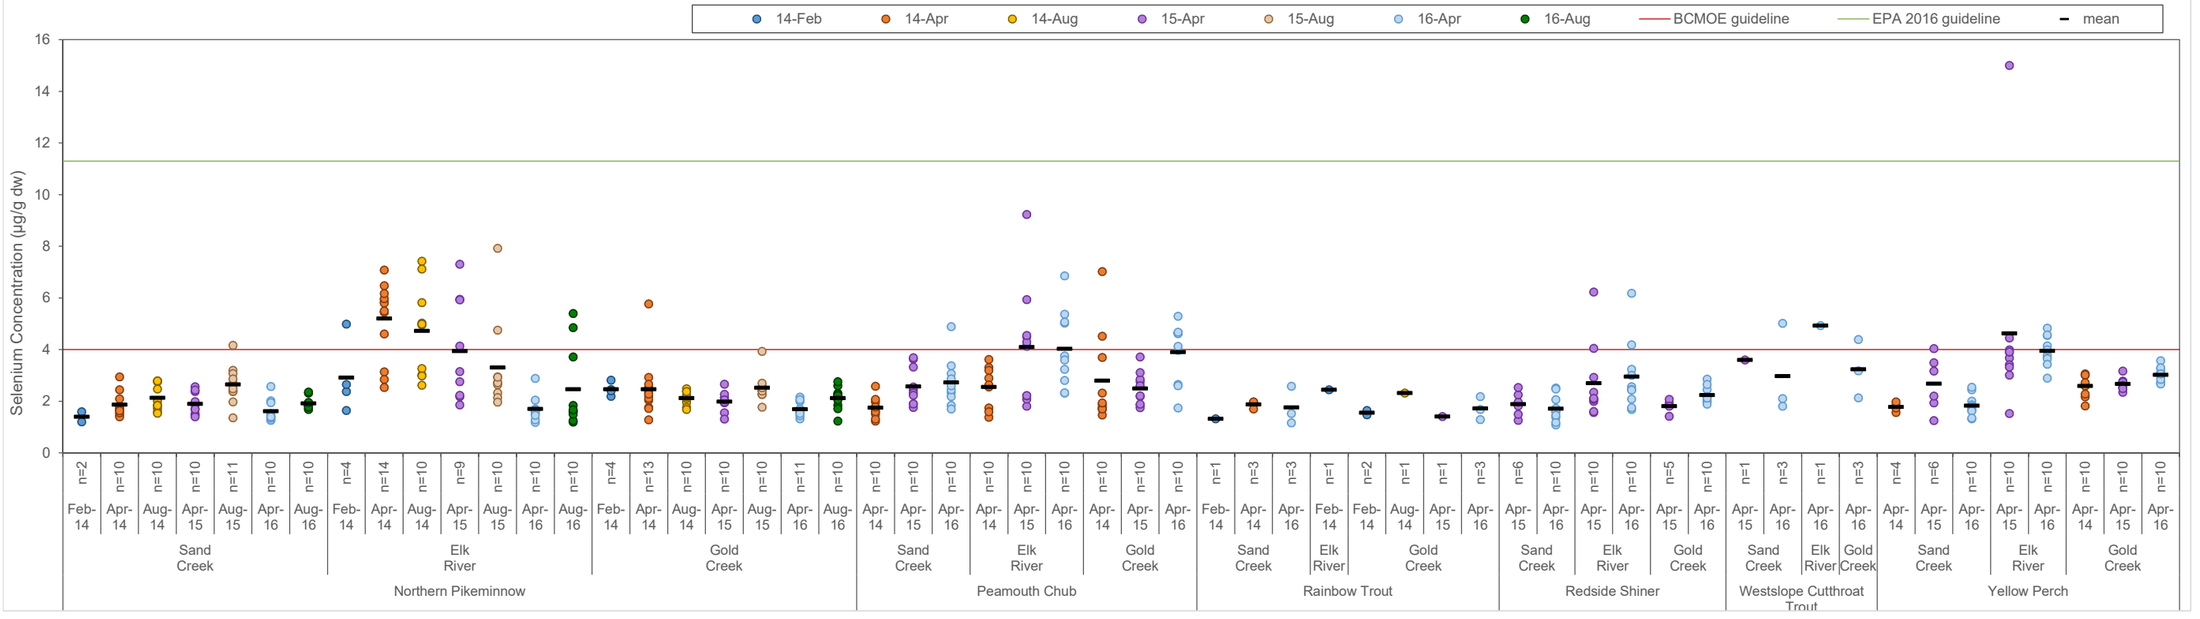


Figure 7.11: Fish Muscle Selenium Concentrations (µg/g dw) in Koocanusa Reservoir, 2014 to 2016

Note: Sand Creek study area is upstream of the Elk River confluence, while the Elk River and Gold Creek study areas are downstream of the Elk River.

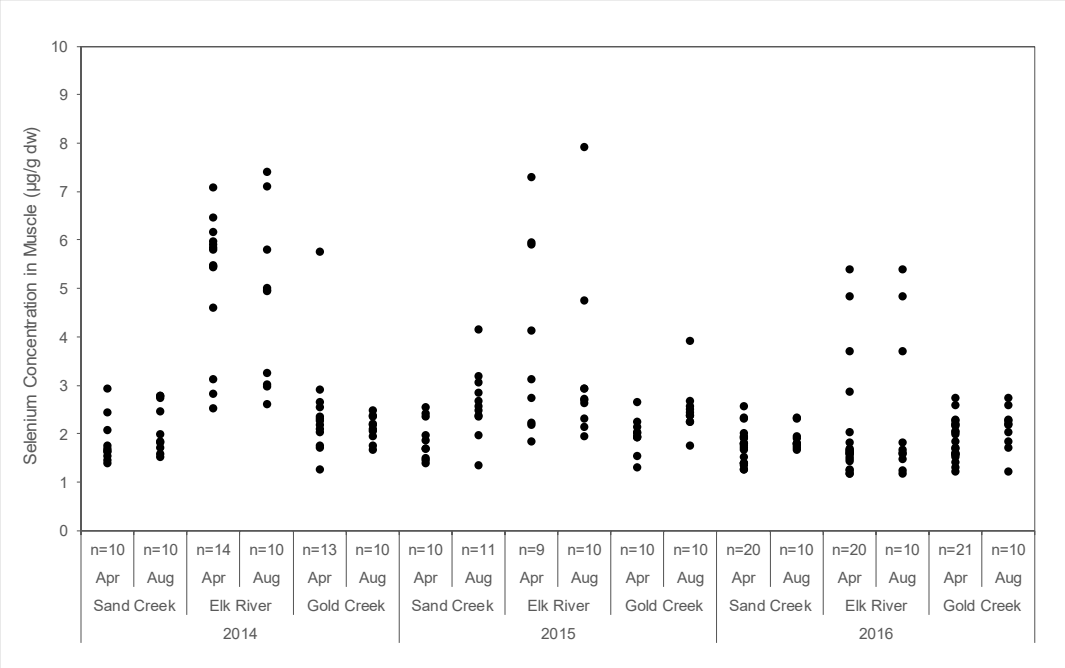

Figure 7.12: Selenium Concentrations (µg/g dw) in Muscle of Northern Pikeminnow Collected in Koocanusa Reservoir, 2014 to 2016

Note: Sand Creek study area is upstream of the Elk River confluence, while the Elk River and Gold Creek study areas are downstream of the Elk River.

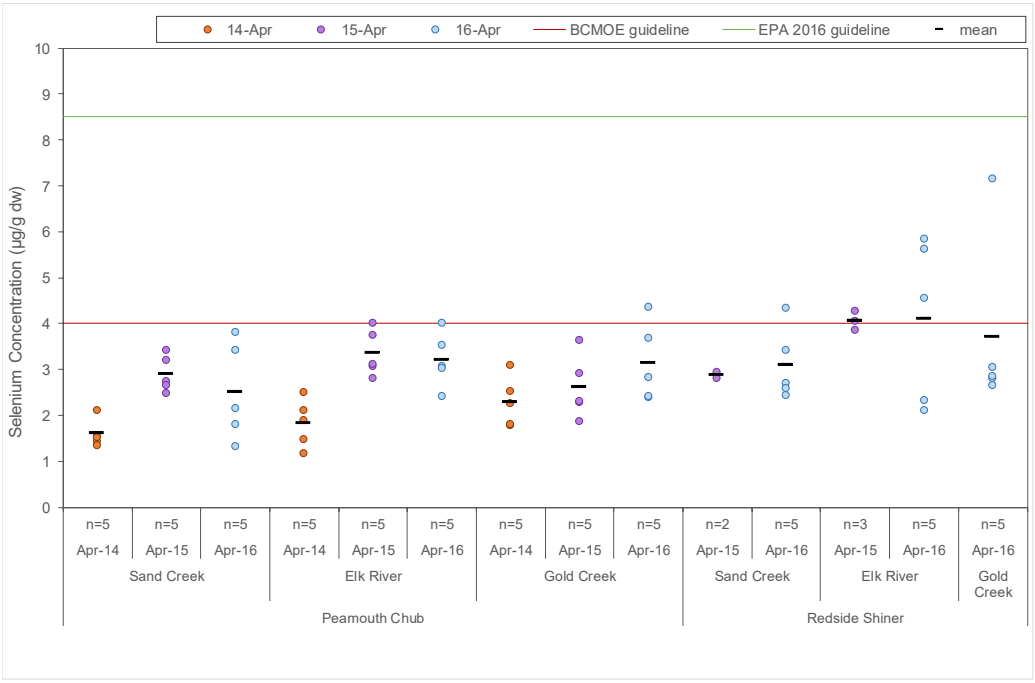

Figure 7.13: Fish Whole Body Selenium Concentrations (µg/g dw) in Koocanusa Reservoir, 2014 to 2016

Note: Sand Creek study area is upstream of the Elk River confluence, while the Elk River and Gold Creek study areas are downstream of the Elk River.

only fish species that had higher ovary selenium concentrations at the Elk River study area compared to the upstream area (Table 7.5). Yellow perch from the Gold Creek study area also had higher ovary selenium concentrations than those at Sand Creek in 2016, but no difference was observed in 2015. No differences in ovary selenium concentration were evident between downstream and upstream areas for peamouth chub. Selenium concentrations in the ovaries of northern pikeminnow and redside shiners were significantly lower at the Gold Creek area than at the Sand Creek area, while no differences were observed for either of these species between the Elk River and Sand Creek areas (Table 7.5).

With the exception of redside shiner and northern pikeminnow all mean ovary selenium concentrations were below the EVWQP Level 1 benchmark for reproductive effects to fish (18 mg/kg dw) and the 2016 USEPA criteria of 15.1 µg/g dw (Figure 7.14). Redside shiner ovary concentrations were above the Level 1 benchmark at both the Elk River and Sand Creek areas in both years they were sampled. Northern pikeminnow had mean ovary selenium concentrations above the Level 1 benchmark only at the Elk River area in one of the three years they were sampled (2014), when ovaries were relatively undeveloped (Appendix Table F.27). Mean selenium concentrations in ovaries of peamouth chub from all areas, particularly in 2015 and 2016, also exceeded the BCMOE guideline of 11 µg/g dw (Figure 7.14). While the mean selenium concentration in ovaries of rainbow trout from Gold Creek in 2016 exceeded the BCMOE guideline, it was based on a sample size of only two, whereas the guideline is intended to be applied to a mean of eight or more samples. Exceedances of tissue selenium benchmarks or guidelines does not necessarily mean that effects will occur as fish species show a range of sensitivities to selenium (USEPA 2016).

7.4.4 Muscle to Ovary Selenium Concentration Ratio

Selenium concentrations were generally highest in ovaries, compared to muscle and whole body samples, which is a common inter-tissue selenium concentration pattern among fish species (i.e., fish ovary-to-muscle selenium concentrations typically range from 1:1 to 7:1 among species; Table 7.6; Appendix Figure F.29). Selenium concentrations in fish ovaries were compared to muscle selenium concentrations for seven species collected in Koocanusa Reservoir[14]. Redside shiners had the highest ovary to muscle selenium concentration ratio at 7.7, while yellow perch had the lowest (1.1; Table 7.6). Except for redside shiner, the ratios observed for species collected in Koocanusa Reservoir spanned the range of those previously documented for other fish species (Table 7.6; Appendix Figure F.29).

[14] Based on only individuals with GSI > 1%, which is considered indicative of active reproductive investment development (Environment Canada 2012).

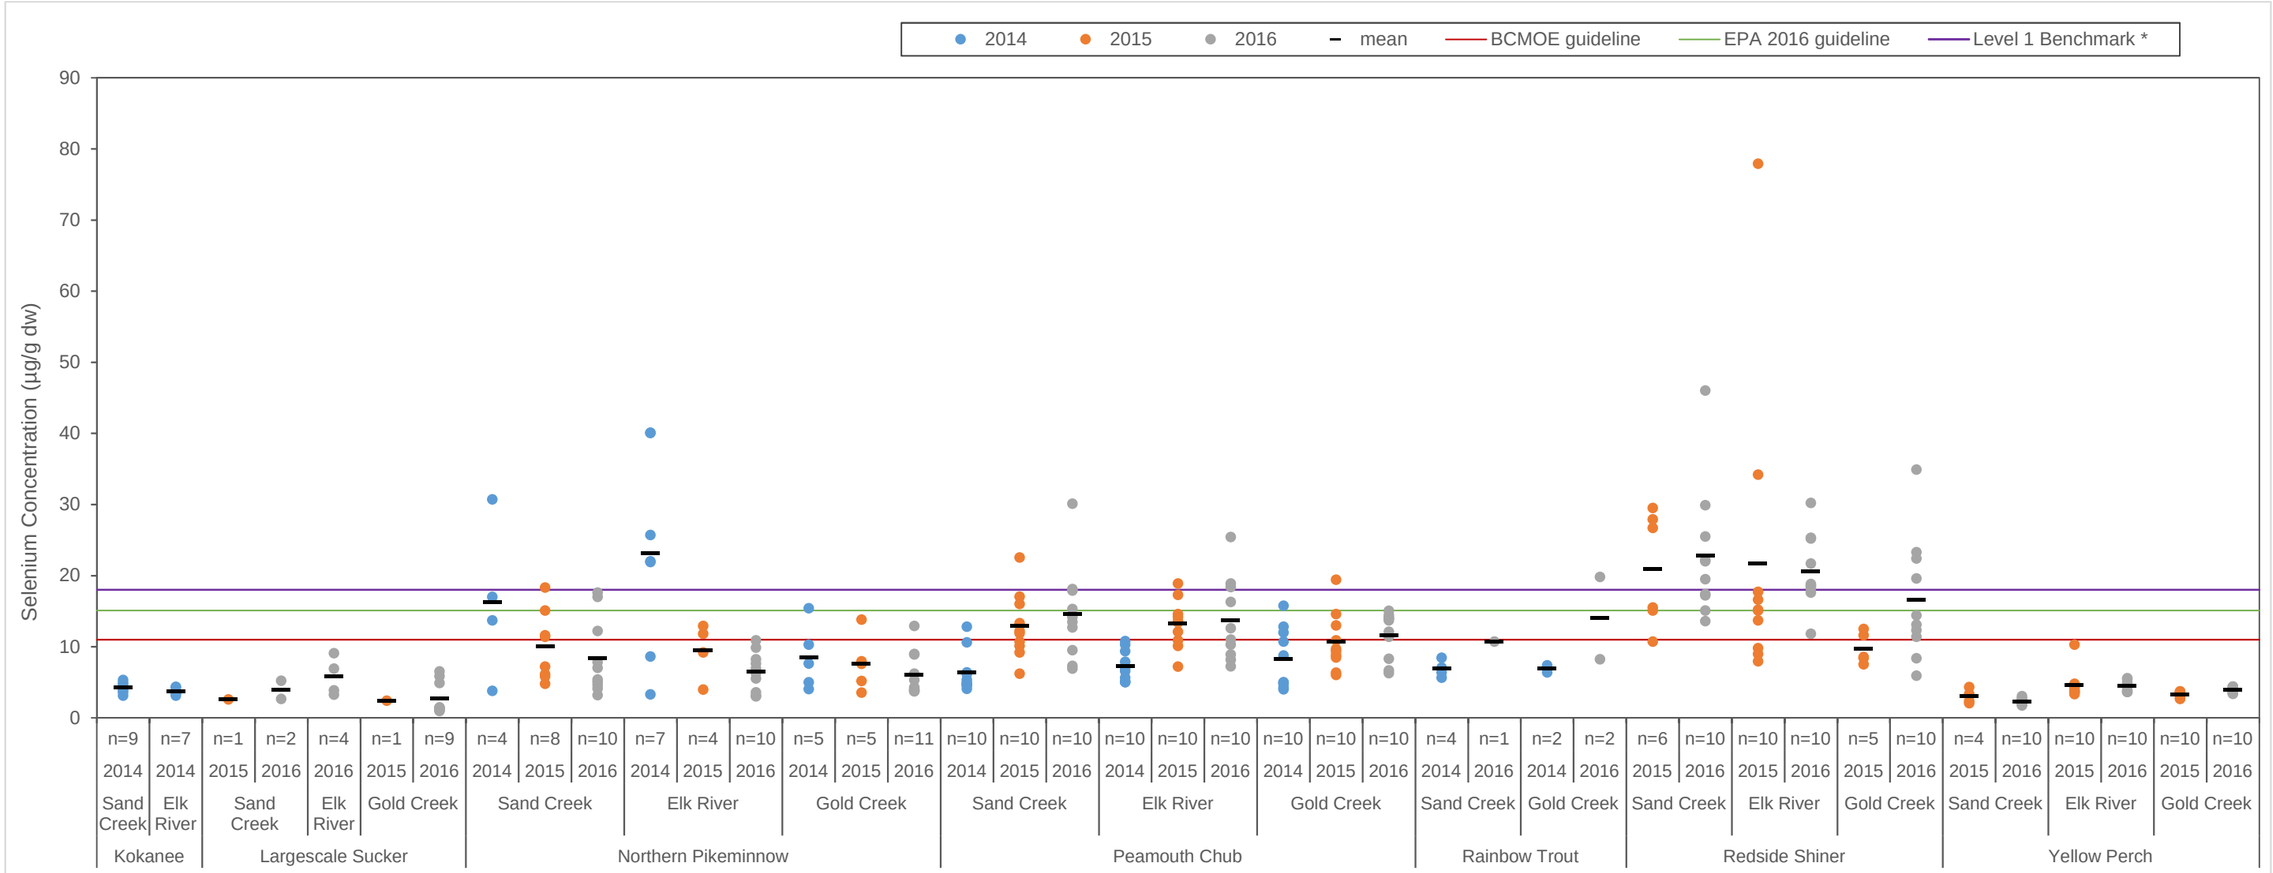

Figure 7.14: Fish Ovary Selenium Concentrations (µg/g dw) in Koocanusa Reservoir, 2014 to 2016

Note: Sand Creek study area is upstream of the Elk River confluence, while the Elk River and Gold Creek study areas are downstream of the Elk River.
* Level 1 benchmark for effects to fish reproduction (Teck 2014)

[a] Ratio of ovary to muscle for individual fish as listed by USEPA (2016)

[b] r^2 presented for significant relationships ($p<0.05$)

[c] Estimated from a figure in Nautilus (2011)

7.5 Mercury Concentrations in Muscle

Elevated mercury concentrations are often observed in predatory fish species in northern lakes due to naturally high mercury levels, atmospheric deposition of mercury, and biogeochemical conditions that favour mercury methylation (Evers et al. 2011). Methylated mercury is bioaccumulated and biomagnified through the food chain resulting in elevated concentrations in larger, older, and more predatory fish (such as burbot and bull trout). Consistent with mercury's known ability to bioaccumulate, concentrations in the muscle of fish from Koocanusa Reservoir were typically higher in larger fish (Appendix Figures F.30 to F.40). Muscle mercury concentrations were consistently higher than the BCMOE guideline for the protection of wildlife (0.033 µg/g ww), assuming all mercury is present as methylmercury (CCME 2000). The only exception was mountain whitefish, where muscle mercury concentrations in most individuals were below the guideline (Appendix Figure F.34). As indicated in the footnote of Section 3.3.2, the metallurgical coal mines in the Elk River watershed are not considered to be a source of mercury.

8 SUMMARY

A three-year study characterizing and comparing chemical and biological conditions in the Canadian portion of Koocanusa Reservoir downstream from the Elk River compared to upstream was completed over the 2014 to 2016 period.

Water quality profiles conducted during biological sampling indicated that the water column was oxygenated with slightly alkaline pH. Concentrations of nitrate, selenium, and sulphate were similar in water samples collected at middle and bottom depths at all downstream sample locations, but were typically lower in samples collected at the surface. Differences between upstream and downstream concentrations were greater in 2016 than 2015 for both nitrate and selenium, but mean concentrations at the downstream areas in 2016 were similar to or less than those observed in 2015. Sulphate concentrations did not differ significantly downstream versus upstream of the Elk River in any years. SPOs for nitrate, selenium, sulphate, and dissolved cadmium were consistently met at the Order station downstream from the Elk River.

Sediment samples collected in the reservoir both downstream and upstream from the Elk River were mostly silt (≥60%), with sand and clay comprising smaller fractions, and TOC concentrations ranging from 0.9 to 1.7%. Concentrations of most metals and PAHs in sediment were higher downstream from the Elk River compared to upstream, but did not increase over the three year study. Concentrations of some metals (upstream and downstream) and PAHs (downstream only) in sediments were also above the lower provincial sediment quality guidelines (i.e., thresholds, below which, aquatic life is protected from adverse effects), but none exceeded the higher guidelines (i.e., thresholds, above which, severe effects to aquatic life are likely to occur).

Low concentrations of phosphorus and chlorophyll-a, along with low seston and zooplankton biomass, all indicated that the reservoir is oligotrophic. Phytoplankton communities in the reservoir were numerically dominated by diatoms, and to a lesser extent, Chrysophytes. There were no significant differences in overall phytoplankton density, biomass, or richness between downstream and upstream areas over the three years. The only difference in community structure was greater Cyanophyte biomass at the downstream area, which was considered to have low ecological significance because this group represented <1% of the community.

The zooplankton community was numerically dominated by rotifers and copepods, with relatively low numbers of cladocerans. No consistent differences were observed between downstream and upstream areas in overall zooplankton density, biomass, richness, or in absolute or relative density or biomass of copepods or rotifers, over the three year study.

Abundance and biomass of cladocerans tended to be lower downstream from the Elk River compared to upstream.

Benthic invertebrate communities were primarily composed of oligochaetes (mostly immature Tubificinae), insects (various species of chironomids), and ostracods in all three sample years. Overall community density and richness did not differ significantly between upstream and downstream areas in any of the three study years. However, community structure differed between areas, particularly with respect to ostracods, which had higher average density at the downstream area (means ranging from 849 to 1,686 per m^2) compared to the upstream area (means of 38 to 333 per m^2) over the three years of study. Densities of oligochaetes were also significantly higher at the downstream area (range of 1,194 to 1,449 per m^2) compared to the upstream area (range of 418 to 1,194 per m^2). Greater abundance of these organisms downstream from the Elk River compared to upstream may be associated with preference for greater depths and finer sediment texture, and/or avoidance of coarser, compacted sediments in the upstream area that dry out during low pool.

Largescale sucker, northern pikeminnow, peamouth chub, redside shiner, and yellow perch were the most commonly captured species all three study areas (i.e., Sand Creek, Elk River, and Gold Creek), with other less-commonly captured species including bull trout, burbot, kokanee, longnose sucker, mountain whitefish, pumpkinseed, rainbow trout, slimy sculpin, and westslope cutthroat trout. Fish health surveys, which focused on endpoints indicative of fish survival (mean age), growth (body size-at-age), reproduction (relative gonad weight) and energy storage (relative liver weight and overall condition), showed no consistent patterns among fish species, sexes, or sampling years that were indicative of influence from the Elk River.

Selenium concentrations in zooplankton were similar between downstream and upstream areas in all three years. In contrast, mean benthic invertebrate tissue selenium concentrations were significantly higher at the downstream area than the upstream area. Concentrations were also greater than the BC interim chronic dietary guideline of 4 µg/g dw, but lower than the Level 1 benchmarks for effects to benthic invertebrates (13 mg/kg dw) and for dietary effects to fish (11 mg/kg dw). Some fish had muscle or whole body concentrations of selenium greater than the BC guideline of 4 µg/g dw, but all were less than the USEPA criterion of 11.3 µg/g dw in muscle and 8.5 µg/g dw in whole bodies (except for a single yellow perch with a muscle selenium concentration of 15.0 µg/g dw). Ovary selenium concentrations were frequently greater than the BC chronic guideline of 11 µg/g dw, but all species except redside shiner and northern pikeminnow had mean ovary selenium concentrations less than the Level 1 benchmark for reproductive effects to fish (18 mg/kg dw), and the 2016 USEPA criterion of 15.1 µg/g dw. Northern pikeminnow had mean ovary selenium concentrations above the Level 1 benchmark at

the Elk River area in only one of the three years they were sampled (2014), when ovaries were relatively undeveloped. Mean redside shiner ovary concentrations were above the Level 1 benchmark at both the Elk River and the Sand Creek areas in both years sampled.

Overall, the data collected during this study will be used as the basis for future study design development for a long-term monitoring program.

APPENDIX A
DATA QUALITY ASSESSMENT

APPENDIX A DATA QUALITY ASSESSMENT

A1 INTRODUCTION

A Data Quality Assessment (DQA) was conducted on data collected for the Koocanusa Reservoir 2014 to 2016 monitoring program. The objective of the DQA is to define the overall quality of the data presented in the report, and, by extension, the confidence with which the data can be used to derive conclusions.

A1.1 Background

A variety of factors can influence the chemical and biological measurements made in an environmental study and thus affect the accuracy and/or precision of the data. Inconsistencies in sampling or laboratory methods, use of instruments that are inadequately calibrated or which cannot measure to the desired level of accuracy or precision, and contamination of samples in the field or laboratory are just some of the potential factors that can lead to the reporting of data that do not accurately reflect environmental conditions. Depending on the magnitude of the problem, inaccuracy or imprecision have the potential to affect the reliability of conclusions made from the data. Therefore, it is important to ensure that monitoring programs incorporate appropriate steps to control the non-natural sources of data variability (i.e., minimize the variability that does not reflect natural spatial and temporal variability in the environment) and thus assure the quality of the data.

Data quality as a concept is meaningful only when it relates to the intended use of the data. That is, one must know the context in which the data will be interpreted in order to establish a relevant basis for judging whether or not the data set is adequate. DQA involves comparison of actual field and laboratory measurement performance to data quality objectives (DQOs) established for a particular study, such as evaluation of method detection limits, blank sample data, data precision (based on field and laboratory duplicate samples), and data accuracy (based on matrix spike recoveries and/or analysis of standards or certified reference materials).

DQOs were established at the outset of the project that reflect reasonable and achievable performance expectations (Table A.1). Programs involving a large amount of samples and analytes usually have some results that exceed the DQOs. This is particularly so for multi-element scans (e.g., ICP scans for metals) since the analytical conditions are not necessarily optimal for every element included in the scan. Generally, scan results may be considered acceptable if no more than 20% of the analytes fail to meet the DQOs. Overall, the intent of comparing data to DQOs was not to reject any measurement that did not meet the DQO, but to ensure any questionable data received more scrutiny to determine what effect, if any, this had on interpretation of results within the context of this project.

A1.2 Types of Quality Control Samples

Several types of quality control (QC) samples were assessed based on samples collected (or prepared) in the field and laboratory. These samples, and a description of each, include the following:

- **Blanks** are samples of de-ionized water and/or appropriate reagent(s) that are handled and analyzed the same way as regular samples. These samples will reflect any contamination of samples occurring in the field (in the case of field or trip blanks) or the laboratory (in the case of laboratory or method blanks). Concentrations of analytes should not be detectable, although a DQO of twice the method detection limit allows for slight "noise" around the detection limit.
- **Field Duplicates** are replicate samples split from a larger homogenized sample that was collected at a randomly selected field station. Data from split samples provides a measure of potential contamination or variability introduced after sampling through analysis.
- **Laboratory Duplicates** are replicate sub-samples created in the laboratory from randomly selected field samples which are sub-sampled and then analyzed independently using identical analytical methods. The laboratory duplicate sample results reflect any variability introduced during laboratory sample handling and analysis and thus provide a measure of laboratory precision.
- **Spike Recovery Samples** are created in the laboratory by adding a known amount/concentration of a given analyte (or mixture of analytes) to a randomly selected test sample previously divided to create two sub-samples. The spiked and regular sub-samples are then analyzed in an identical manner. The spike recovery represents the difference between the measured spike amounts (total amount in spiked sample minus amount in original sample) relative to the known spike amount (as a percentage). The analysis of spiked samples provides an indication of the accuracy of analytical results.
- **Certified Reference Materials** are samples containing known chemical concentrations that are processed and analyzed along with batches of environmental samples. The sample results are then compared to target results to provide a measure of analytical accuracy. The results are reported as the percent of the known amount that was recovered in the analysis.

Two additional types of QC, specific to benthic invertebrate or plankton community samples, include:

- **Organism Recovery Checks** for benthic invertebrate community samples. This involves the re-processing of previously sorted material from a randomly selected sample to determine the number of invertebrates that were not recovered during the original sample processing. The reprocessing is conducted by an analyst not involved during the original processing to reduce bias. This check allows the determination of accuracy through assessment of recovery efficiency.
- **Sub-Sampling Error** is assessed for studies in which benthic invertebrate or plankton community samples require sub-sampling (due to large sample volume and/or organism density). By comparing the numbers of organisms recovered between at least two sub-samples, this measure provides an estimate of laboratory precision. Therefore, sub-sampling error provides a measure of analytical accuracy and precision. The processing of an entire benthic invertebrate community sample in representative fractions also allows an evaluation of sub-sampling accuracy.

A2 WATER SAMPLES

Water chemistry samples collected from 2014 to 2016 were taken in accordance with Teck's Annual Water Quality Monitoring Report (Teck 2016b, 2017). Associated QC measures were taken by the analytical laboratory and the field crew and the results from the DQA were included in the aforementioned reports.

A3 SEDIMENT SAMPLES

Sediment chemistry samples collected from 2014 to 2016 were analyzed by ALS Environmental (Calgary, Alberta).

A3.1 Method Detection Limits

MDLs achieved for sediment sample analyses were at or below the target concentrations, with few exceptions. In all three years (2014 to 2016), the MDL was above target concentrations for bismuth, magnesium, phosphorus, strontium, and tin (Table A.2). Additionally, with the analysis of polycyclic aromatic hydrocarbons in 2015 and 2016, targets MDLs were not achieved for acenaphthene, acenaphthylene, and diebnz(a,h)anthracene. However, MDLs for all analytes were below the corresponding guidelines for protection of aquatic health so the reported results can still be evaluated relative to guidelines.

A3.1.1 Method Blanks

Laboratory blank samples were analyzed and reported along with sediment samples in all three samples years. Concentrations of all analytes were reported as being less than the MDL, indicating no inadvertent sample contamination (Table A.3).

A3.2 Data Precision

A3.2.1 Precision Associated with Field Duplicate (Split) Samples

One sediment sample was split in the field in each of the three years to create field duplicates. There was good agreement (<40% RPD) in analyte concentrations for each set of duplicate results (Table A.4). Exceptions were sodium and tin measurements made in 2014, but neither substance has a sediment quality guideline or is considered a mine-related constituent of concern. Overall, the data suggest that reported results were reasonably precise representations of conditions at the time of sampling.

A3.2.2 Laboratory Precision

Close agreement was achieved between laboratory duplicate samples for all three years of analysis, providing further evidence that reported sample results were associated with good analytical precision (Table A.5).

A3.3 Laboratory Accuracy

Recoveries of certified reference materials were all within the target ranges (Table A.6), indicating excellent analytical accuracy.

A4 PLANKTON SAMPLES

Tissue chemistry of zooplankton samples was analyzed by the University of Missouri-Columbia Research Reactor Center (MURR; Columbia, Missouri). Phytoplankton and zooplankton community samples were analyzed by Plankton R Us (Winnipeg, Manitoba).

A4.1 Method Detection Limits for Zooplankton Tissue Chemistry

Method detection limits for analytes measured in zooplankton tissue samples were variable over the three year study (2014 to 2016; Table A.7), but were sufficiently low to report quantifiable tissue concentrations of all analytes (Table G.1).

A4.2 Laboratory Accuracy of Zooplankton Tissue Chemistry Analysis

Accuracy of tissue chemistry data was determined based on recoveries of analytes in liver samples analyzed concurrently with the zooplankton tissue samples (i.e., SRM 1577 bovine liver from National Institute of Standards and Technology, and CRM DOLT-4 and DOLT-5 dogfish liver from the National Research Council). The DQO was recovery of 70 – 130% of the certified value in each sample. Some elements listed on the certificates of analysis are lower-confidence values or unconfirmed results presented for informational purposes, rather than certified values (i.e., the target value may not be accurate). These values were also provided for comparison purposes, but were not used to judge acceptability of data.

Over the three year study, recoveries of metals from CRMs almost all metals met the DQO of 70 to 130% (Table A.8a to c). In particular, reported selenium concentrations were consistently within the certified range of concentrations. Selenium is the tissue constituent of greatest relevance to the project. The results indicated good analytical accuracy associated with analysis of zooplankton tissue samples.

A4.3 Laboratory Precision for Zooplankton Tissue Chemistry Analysis

One set of laboratory duplicate samples was completed for zooplankton tissue analysis. All The DQO of RPD ≤30% was met for all analytes (Table A.9). As such, laboratory precision associated with analysis of zooplankton tissue samples was considered good.

A4.4 Laboratory Precision for Plankton Community Analyses

One zooplankton sample collected during each of the August field programs in 2014, 2015 and 2016 was randomly selected by the laboratory for duplicate analysis of community structure (Plankton R Us). The relative percent difference between replicates was computed at the species and group level, and compared to the DQO (Tables A.10 and A.11). Results indicated

fairly consistent findings at the lowest practical level (LPL) throughout the three year study, although RPDs for the densities of some organisms, particularly those present in low abundance, exceeded the DQO (Table A.10). Comparisons at group level showed good agreement between the duplicate samples, with the exception of the rotifers in 2015 (Table A.11). The results indicate adequate laboratory precision for the purposes of this project, because statistical comparisons among areas and years focused on major group densities.

One phytoplankton sample collected during each of the August field programs in 2014, 2015 and 2016 was randomly selected by the laboratory for duplicate analysis of community structure. The relative percent difference between duplicates was computed at the species and group level and compared to the DQO. Very few replicates met the DQO at the species level (Table A.12). At the major group level, the DQO was met for five of the seven groups in 2014 and 2016, while duplicate results for only three of seven groups met the DQO in 2015 (Table A.13). Poor agreement between duplicate results indicates relatively large sub-sampling error, especially at more detailed levels of taxonomy. This may be due to incomplete homogenization of the sample prior to subsampling, and/or because only a very small portion of a collected sample is assessed (e.g., 10 mL aliquots), so between-sub-sample differences in counts (especially for rarer taxa) become exaggerated once multiplied up to a per-litre density basis. Similar QC issues were recently reported for laboratory analyses of periphyton samples (Minnow and Larratt 2016).

A5 BENTHIC INVERTEBRATE SAMPLES

Benthic invertebrate tissue chemistry samples were analyzed by MURR (Columbia, Missouri). Benthic invertebrate community samples were analyzed by ZEAS Inc. (Bolton, Ontario).

A5.1 Method Detection Limits for Benthic invertebrate Tissue Chemistry Analysis

Method detection limits for analytes measured in benthic invertebrate tissue samples were variable over the three year study (2014 to 2016) (Table A.14), but were sufficiently low to quantify concentrations of all analytes (Table G.1).

A5.2 Laboratory Precision and Accuracy for Benthic Invertebrate Tissue Chemistry Analysis

Benthic invertebrate tissue samples were analyzed at the same time as the fish tissue samples, so the QA/QC results reported in Sections A5.2 and A.5.3 apply to benthic invertebrate samples.

A5.3 Laboratory Precision and Accuracy for Benthic Invertebrate Community Analyses

Percent recovery of organisms was excellent in all three study years, ranging from 95% to 100% among samples, and all values were well above the corresponding DQO of ≥ 90% (Table A.15a).

Sub-sampling error was not estimated in 2014 or 2015 because all samples were sorted and enumerated in their entirety. In 2016, subsampling error was estimated for 1 of the 10 samples. Subsample precision and accuracy were excellent based on good agreement between the two sub-samples for organism abundance (Table A.15b).

A6 FISH SAMPLES

Metal concentrations were analyzed in fish tissues (i.e., bull trout [BT], burbot [BB], kokanee [KO], largescale sucker [CSU], mountain whitefish [MW], northern pikeminnow [NSC], peamouth chub [PCC], rainbow trout [RT], redside shiner [RSC], westslope cutthroat trout [WCT], yellow perch [YP]) were analyzed in 2014, 2015 and/or 2016 by MURR (Columbia, MO). The benthic invertebrate tissue were analyzed at the same time, so the QA/QC applies, as well. Resulting QA/QC is discussed collectively in the following sections.

A6.1 Method Detection Limits

MDLs for elements measured in fish tissue samples were variable, but were typically very low (Table A.16). Selenium, which was the main tissue constituent of interest for this project, had sufficiently low MDLs to results in quantifiable concentrations in fish tissue samples and allow for comparison to tissue guidelines and site-specific benchmarks (Tables G.2 to G.11).

A6.2 Laboratory Precision

Replicate digestions of several fish muscle, ovary, and whole body samples were prepared for analysis in all three study years (2014 to 2016; Table 17a,b,c, Table 18a,b,c and Table 19). Fish muscle and ovary samples were homogenized within their freeze drying vessels using a combination of pre-cleaned plastic lab spatulas and glass stir rods. This homogenization technique may not have been entirely adequate for the fish muscle samples as small flakes of connective tissue were still visible in the muscle powder. This is most likely the cause of some inconsistency of the replicate results for a few elements in fish muscle (Table A.17a,b,c). However, duplicate results for were comparable for most analytes, and showed consistently good agreement for selenium concentrations (Tables A.17a,b,c and A.18a,b,c). Therefore, the precision of tissue chemistry results for fish and benthic invertebrates was considered acceptable.

Replicate digestions of nine whole body fish samples were prepared from 2014 to 2016. Whole-bodied fish samples were homogenized using a cryogenic mixer mill, which effectively pulverized the samples into a fine, frozen powder. This resulted in very homogenous samples, which is reflected in the fact that very few substances exceeded the DQO by only a minor amount in replicate analyses (Table A.19). There was good agreement in selenium concentrations between duplicate samples. Overall, the results of replicate analyses indicated acceptable precision of analyses.

A6.3 Laboratory Accuracy

Accuracy of tissue chemistry data was determined based on recoveries of analytes in liver samples analyzed concurrently with the fish tissue samples (i.e., SRM 1577 bovine liver from National Institute of Standards and Technology, and CRM DOLT-4 and DOLT-5 dogfish liver from the National Research Council). The DQO was recovery of 70 – 130% of the certified value in each sample. Some elements listed on the certificates of analysis are lower-confidence values or unconfirmed results presented for informational purposes, rather than certified values (i.e., the target value may not be accurate). These values were also provided for comparison purposes, but were not used to judge acceptability of data.

Matrix spikes using approximately 3 ppm of two multi-element solutions (together containing many, but not all, analytes) were also performed on muscle fillet, ovary and whole body samples, but could not be performed on muscle plug samples based on their small size.

Results for chromium and mercury in SRM 1577 exceeded the DQO in most instances compared to certified values in all three study years (Table A.20,a,b,c). However, results for chromium and mercury in DOLT-4 and DOLT-5 were within the acceptable range relative to certified or informational values (Table A.20,a,b,c). All other elements met the DQO for all analyses, with a few minor exceptions where recovery was just outside of the acceptable range. Selenium concentrations, which were of particular relevance in this project, met the DQO except for a small proportion of instances in which the reported concentrations slightly overestimated the actual sample amount. This means that, if anything, sample concentrations associated with the project may slightly overestimate actual tissue concentrations and the project results will be conservative in terms of estimating potential selenium-related risks to fish or their consumers.

Matrix spike recoveries almost always met the DQO of 70-130%, with the exception of zirconium where the recovery was often not completely recovered in all three years of the study (Table A.21a,b,c). Spike recovery results for some elements were omitted by MURR because the high or variable level of the element in the unspiked sample precluded accurate measurement of percent recovery (Table A.21a,b,c). Recoveries of selenium in matrix spikes were consistently good. Overall, the results for analysis of matrix spikes and certified reference materials indicated acceptable analytical accuracy for fish tissue samples.

A7 DATA QUALITY STATEMENT

The quality of the data collected for this project was considered acceptable to serve the project objectives, except that phytoplankton community results should be interpreted with caution based on poor agreement on taxon densities between laboratory subsamples.

Table A.1: Data Quality Objectives for Samples Collected in Koocanusa Reservoir, 2014 to 2016

Quality Control Measure	Quality Control Sample Type	Study Component			
		Sediment Quality	**Phytoplankton and Zooplankton Community**	**Benthic Invertebrate Community**	**Tissue Chemistry**
Method Detection Limits (MDL)	Comparison of actual MDL versus target MDL	MDL for each parameter should be at least as low as applicable guidelines, ideally ≤1/2 the LEL guideline value[a]	NA	NA	NA
Blank Analysis	Laboratory Blank	Within target range of ≤2x the MDL	NA	NA	NA
Field Precision	Field Duplicates (split samples)	≤40% RPD[b]	NA	NA	NA
Laboratory Precision	Laboratory Duplicates	≤35% RPD[b]	≤30% RPD[b]	≤20% RPD[b]	≤30% RPD[b]
Accuracy	Recovery of Matrix Spikes	NA	NA	NA	70-130%
	Recovery of Certified Reference Material, QC Standards	Within laboratory target range of 70-130%[c]	NA	NA	70-130%
	Sub-Sampling Accuracy	NA	NA	Sub-sample estimate is within 80% to 120% of total sample abundance	NA
	Organism Recovery	NA	NA	≥90%	NA

[a] or should meet target MDLs provided by the laboratory, if a guideline does not exist for the substance.

[b] RPD - Relative Percent Difference

[c] some variations occur with the DQO, which are indicated on Appendix Table A.6.

NA - Not Applicable

Table A.2: Laboratory Method Detection Limits (MDLs) for Sediment Samples Relative to Targets and Sediment Quality Guidelines

	Analyte	Units	BCSQG[a]	Method Detection Limit

Table A.15a: Benthic Invertebrate Community Organism Recoveries

Station ID	Number of Organisms Recovered (initial sort)	Number of Organisms in Re-sort	Percent Recovery
2014			
T2-4	130	130	100.0%
T4-6	487	491	99.2%
		Average % Recovery	99.6%
2015			
TN-3	87	92	94.6%
T4-2	361	363	99.4%
		Average % Recovery	97.0%
2016			
TN-1	184	186	98.9%
T4-4	488	497	98.2%
		Average % Recovery	98.6%

Note: Highlighted values did not meet the data quality objective of ≥90% recovery.

Table A.15b: Calculation of Subsampling Error for Benthic Macroinvertebrate Samples

Station	Whole Organisms	Number of Organisms in Fraction 1	Number of Organisms in Fraction 2	Number of Organisms in Fraction 3	Number of Organisms in Fraction 4	Actual Density*	Precision % RPD range)		Accuracy %	
							min [a]	max [b]	min	max
T4-4	-	242	255	-	-	-	NA	5.1	97.4	103.0

Note: Highlighted values did not meet the data quality objectives of ≤20% for precision or within 80% to 120% for accuracy.

* whole large organisms excluded in calculations.

[a] min = minimum absolute % error.

[b] max = maximum absolute % error.

Table A.15c: Sample Fractions Sorted from Koocanusa Reservoir, 2016

Station	Fraction Sorted	Station	Fraction Sorted
TN-1	Whole	T4-2	Whole
TN-2	Whole	T4-3	Whole
TN-3	Whole	T4-4	Whole [c]
TN-4	Whole	T4-5	Whole
TN-5	1/2	T4-6	Whole

[c] two halves sorted for subsampling error calculations.

QA/QC Notes

Pupae were not counted toward total number of taxa unless they were the sole representative of their taxa group.
Immatures were not counted toward total number of taxa unless they were the sole representative of their taxa group.
Correction to 2015 data based on 2016 reference listed below
All *Cyprinotus* are *Isocypris*
All *Limnocythere* are *Cytherissa lacustris*
All *Ilyocypris* are *Limnocythere*
Keys to Nearctic Fauna 2016.

Note: Highlighted values did not meet the data quality objective of 70 - 130% recovery.

* Not spiked (the element was not included in the multi-element spike solution).
† Spike too small (the concentration of the element spiked into sample was less than 50% of the average concentration measured in the replicates).
‡ High variability in replicates (the spike level was less than 2x the standard deviation of replicates).
§ Only one unspiked replicate was used for this element because the second replicate was digested in a vessel with known, significantly high background levels of this element. Thus the standard deviation of the replicates could not be accurately determined.

Note: Highlighted values did not meet the data quality objective of 70 - 130% recovery.

* Not spiked (the element was not included in the multi-element spike solution).
† Spike too small (the concentration of the element spiked into sample was less than 50% of the average concentration measured in the replicates).
‡ High variability in replicates (the spike level was less than 2x the standard deviation of replicates).
§ Only one unspiked replicate was used for this element because the second replicate was digested in a vessel with known, significantly high background levels of this element. Thus the standard deviation of the replicates could not be accurately determined.

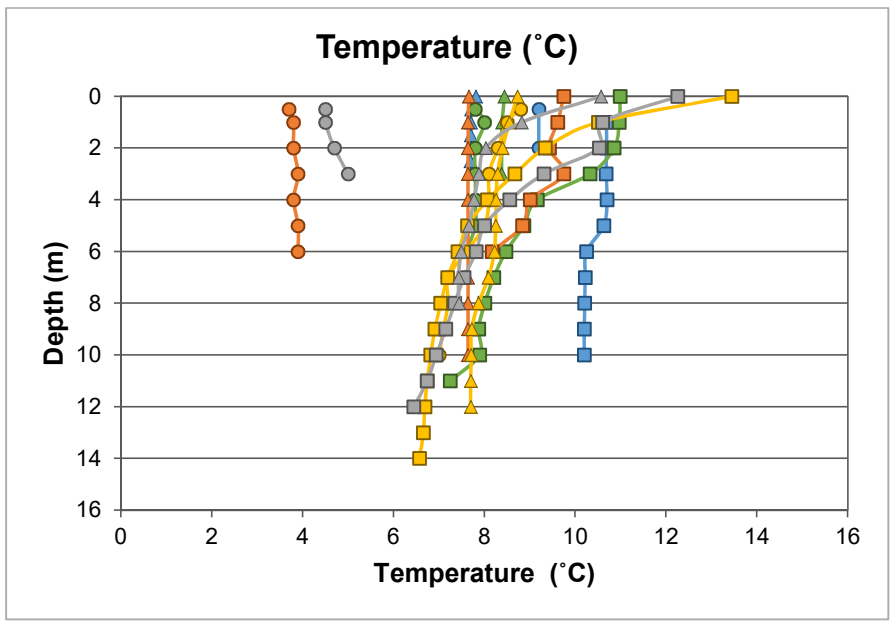
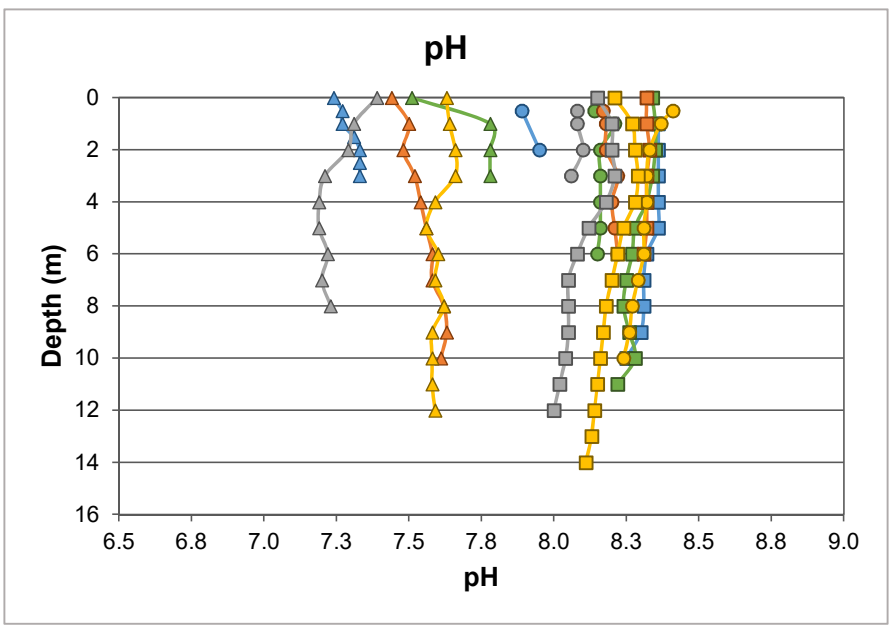
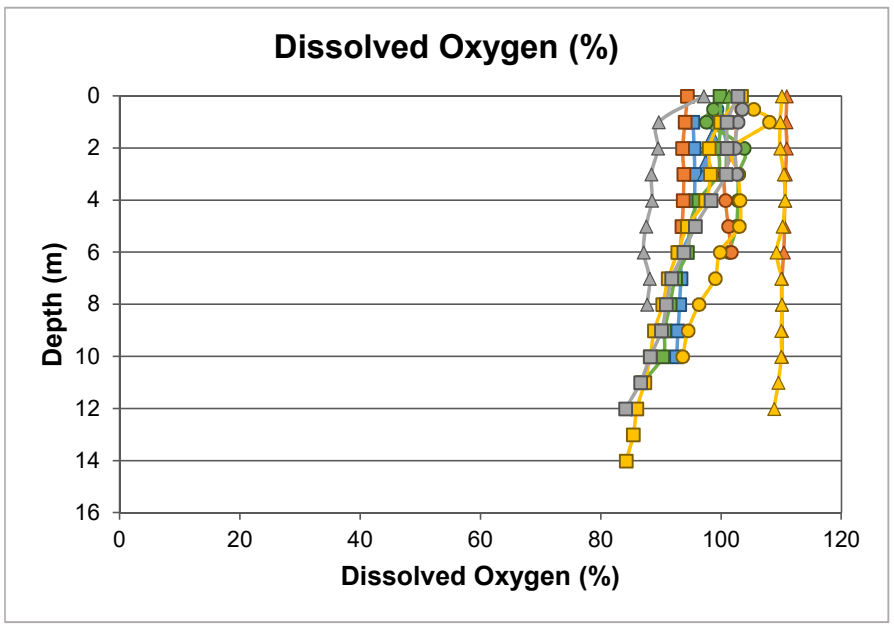
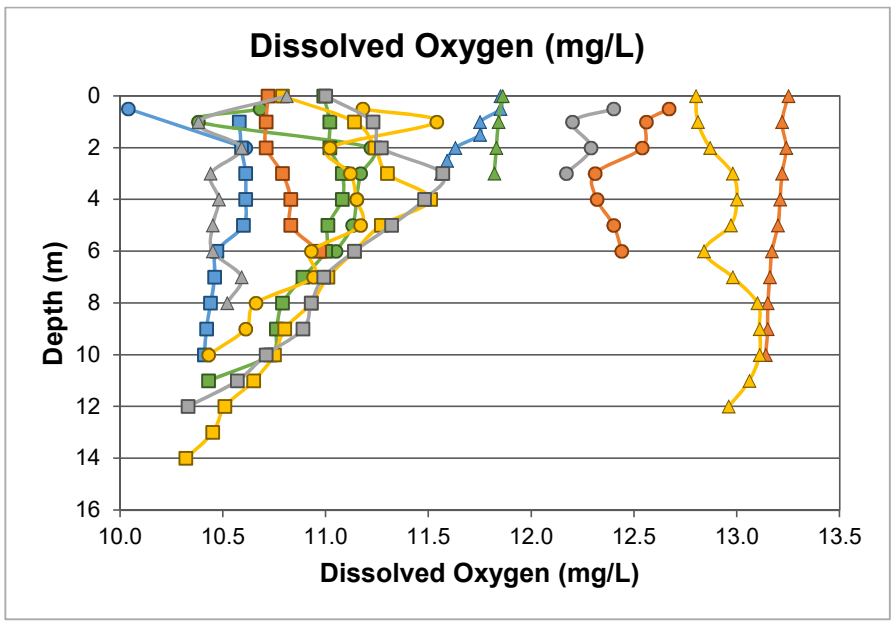
Figure B.1: ***In situ*** **Water Quality Profiles Conducted at Sand Creek, Elk River, and Gold Creek Areas in Koocanusa Reservoir, February 2014 and 2015**









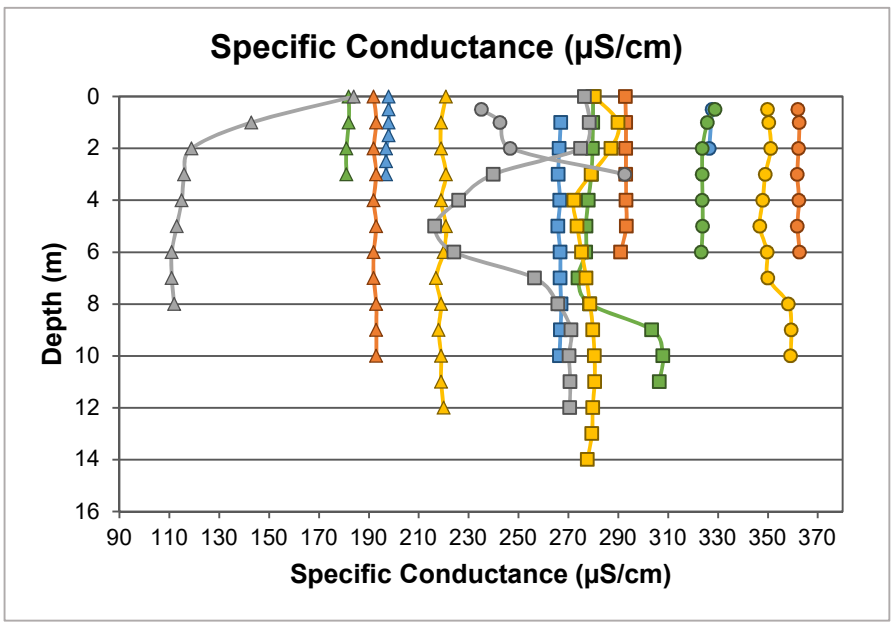


Figure B.2: ***In situ W*** **ater Quality Profiles Conducted at Sand Creek, Elk River, and Gold Creek Areas and at the Upstream (T2/TN) and Downstream (T4) Sampling Stations in Koocanusa Reservoir, April 2014, 2015 and 2016**

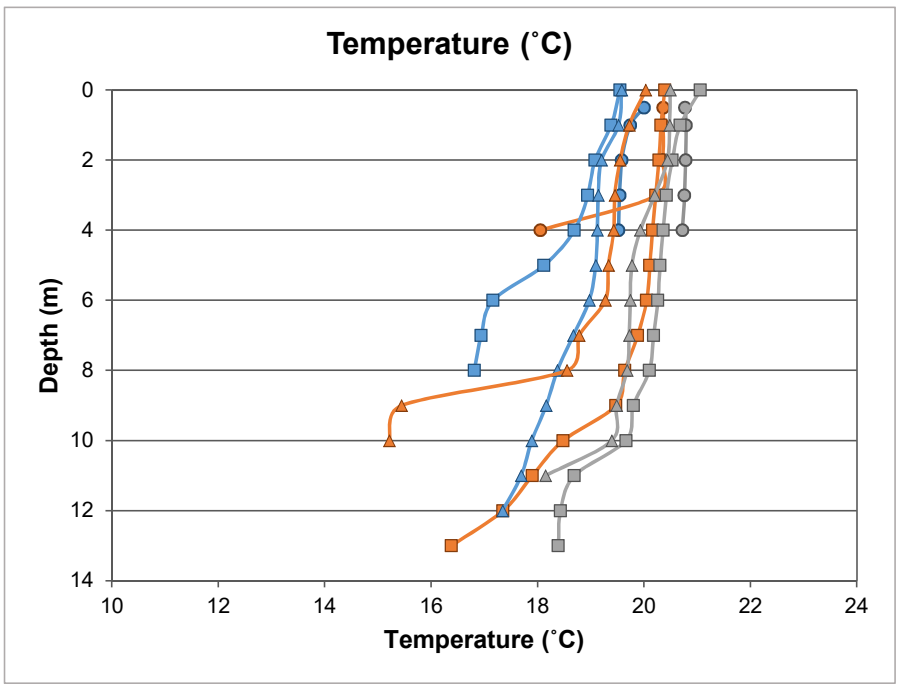

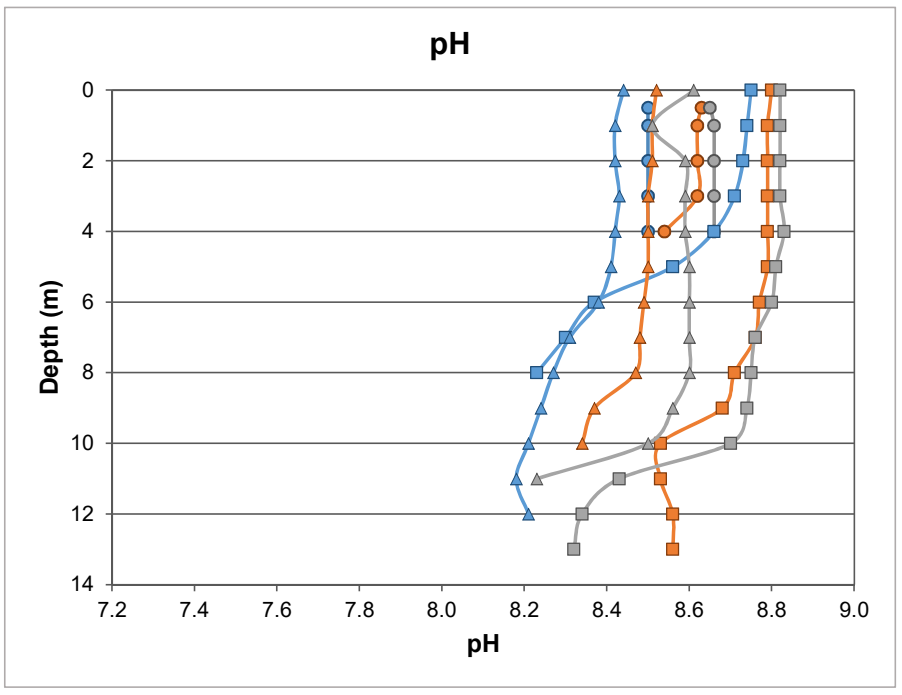

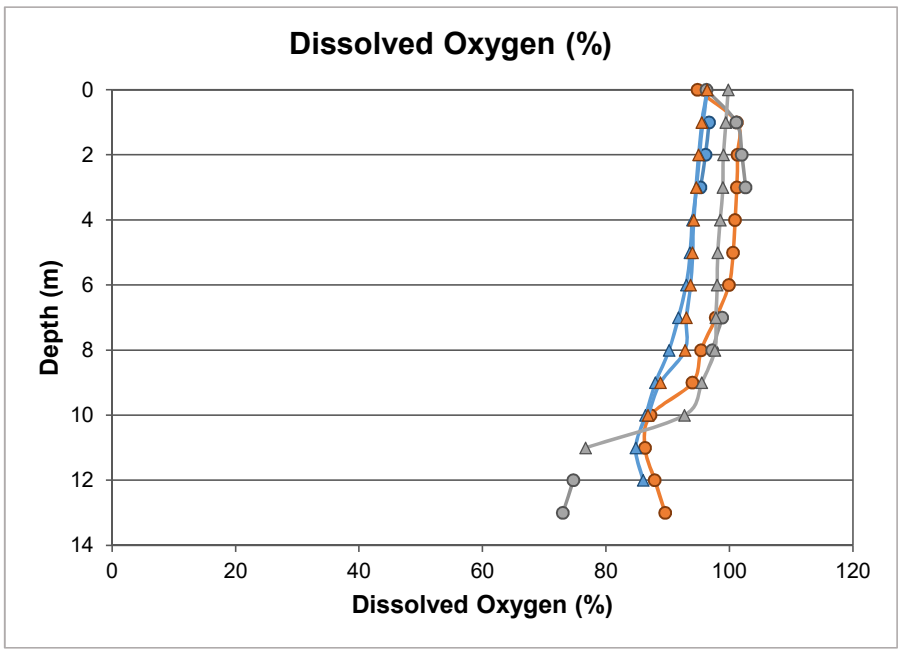

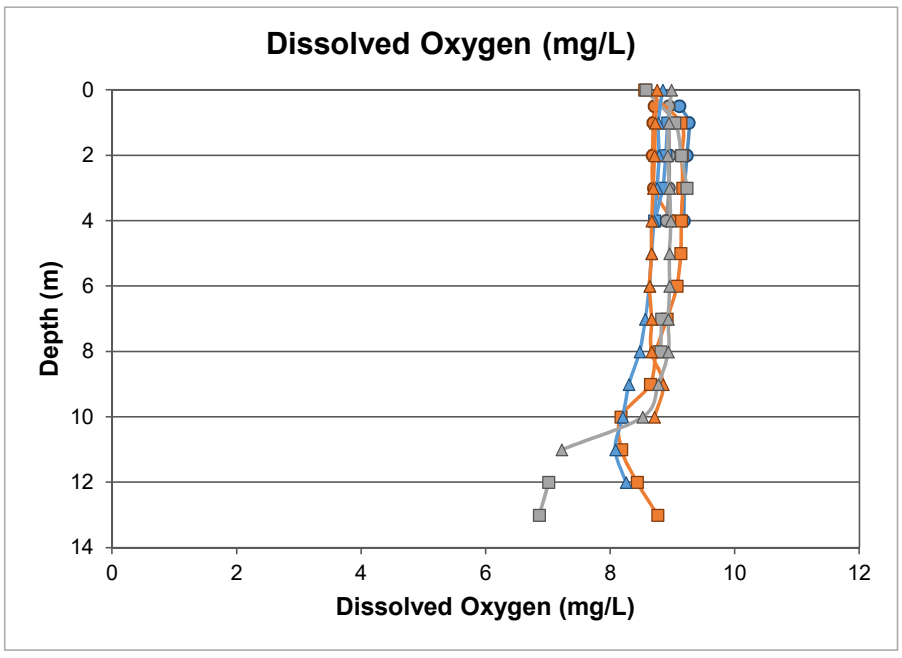

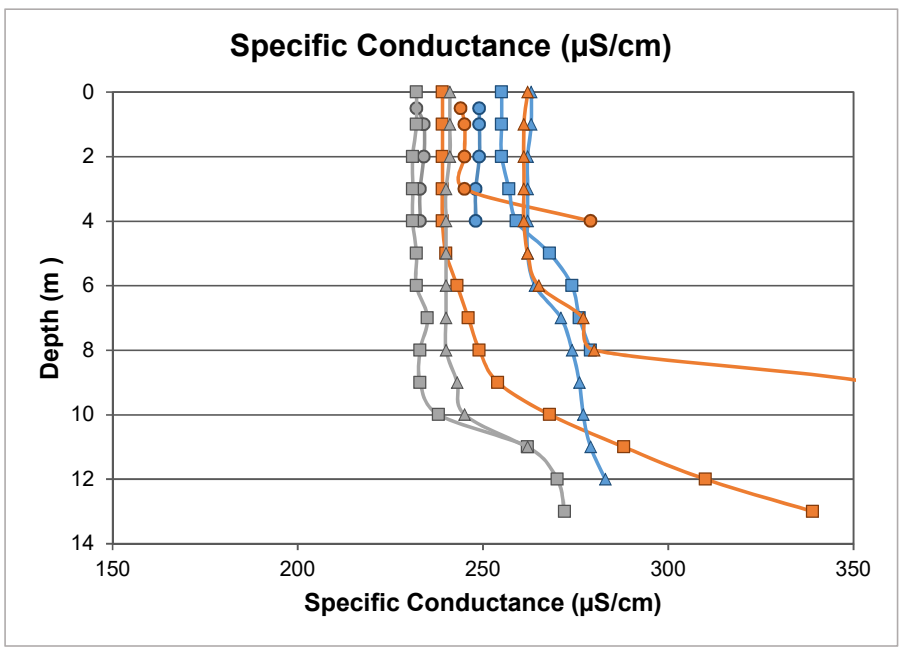

Figure B.3: ***In situ*** **Water Quality Profiles Conducted at Sand Creek, Elk River, and Gold Creek Areas in Koocanusa Reservoir, August 2014, 2015 and 2016**

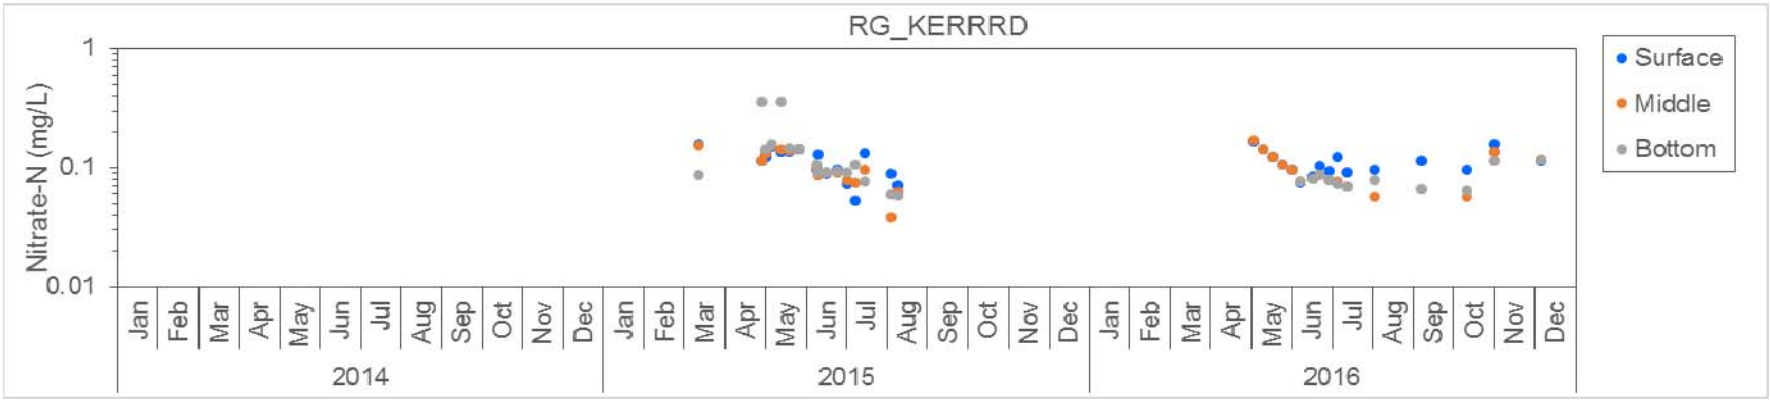

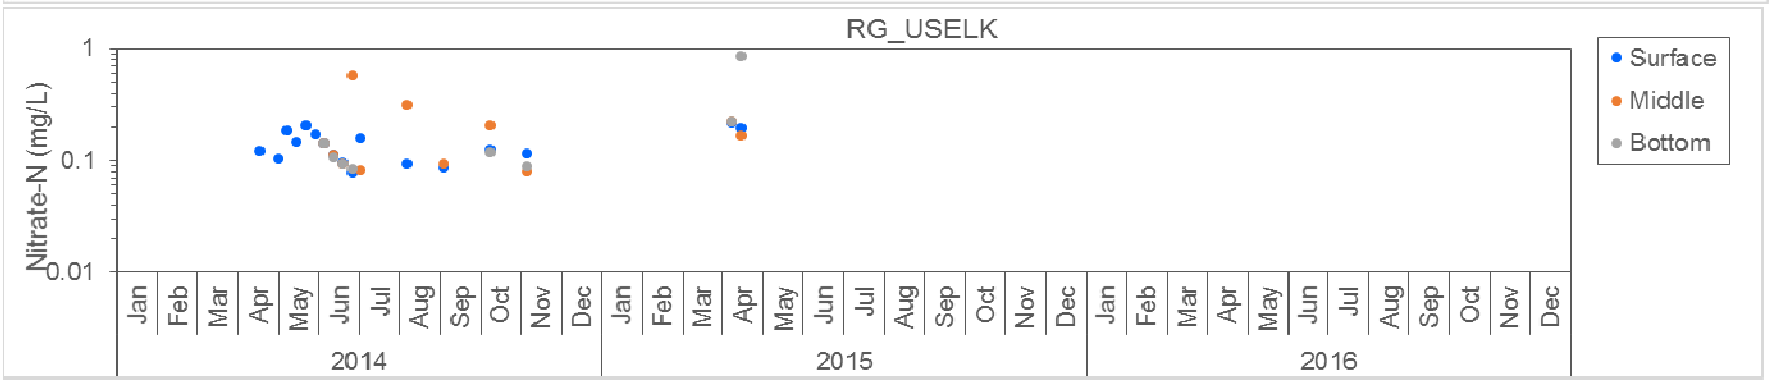

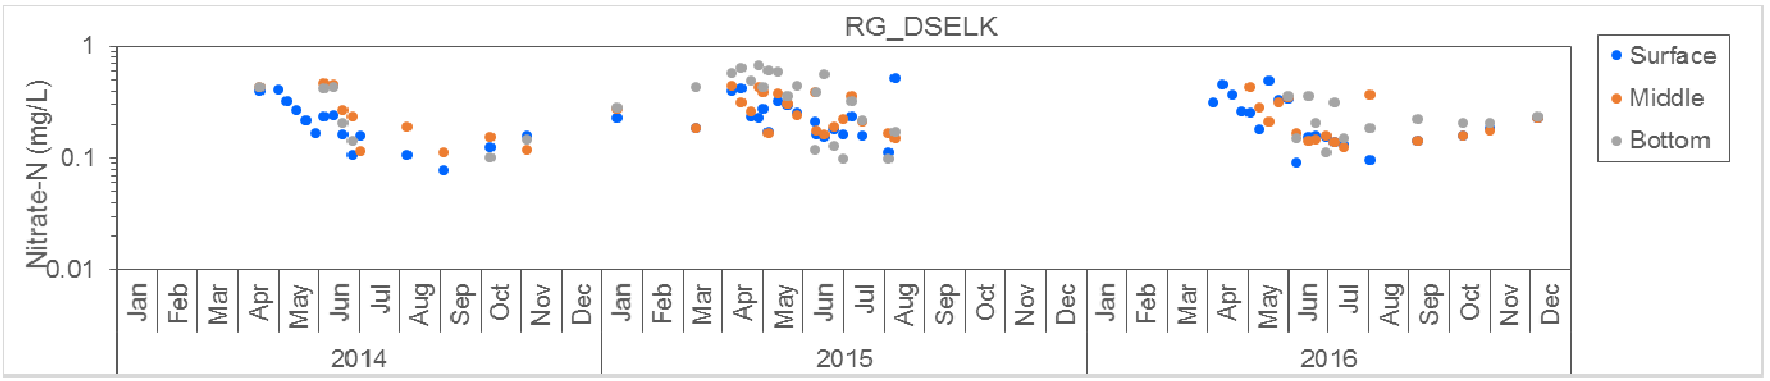

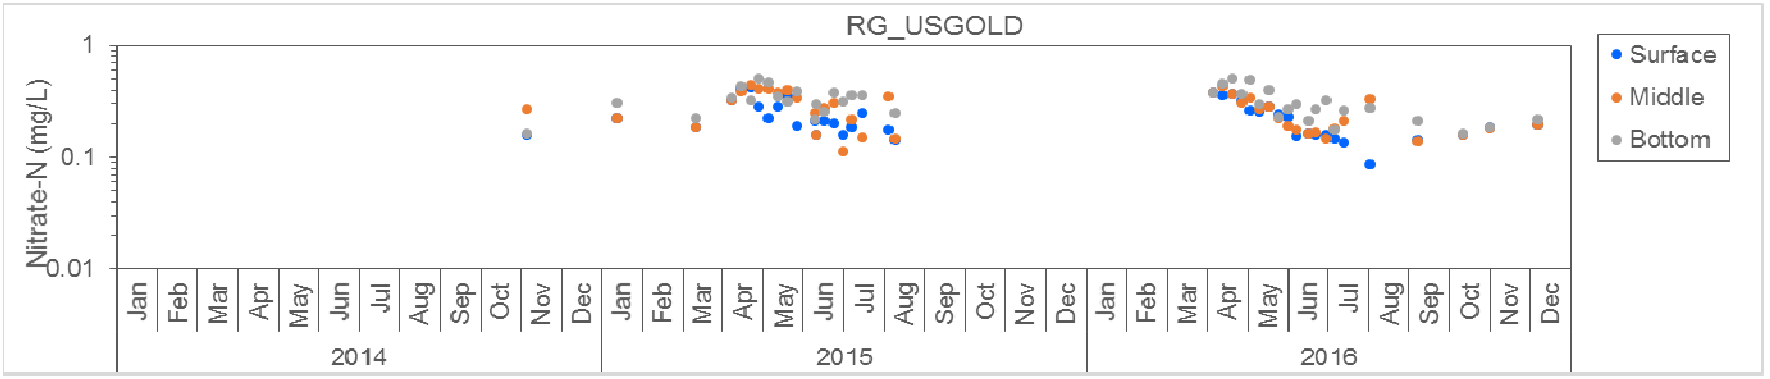

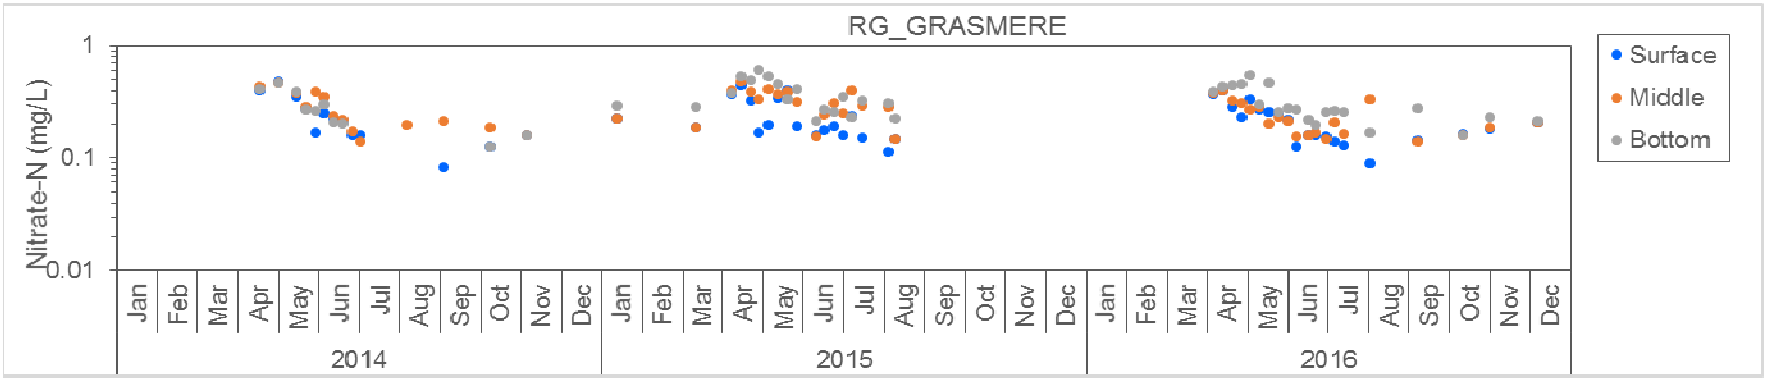

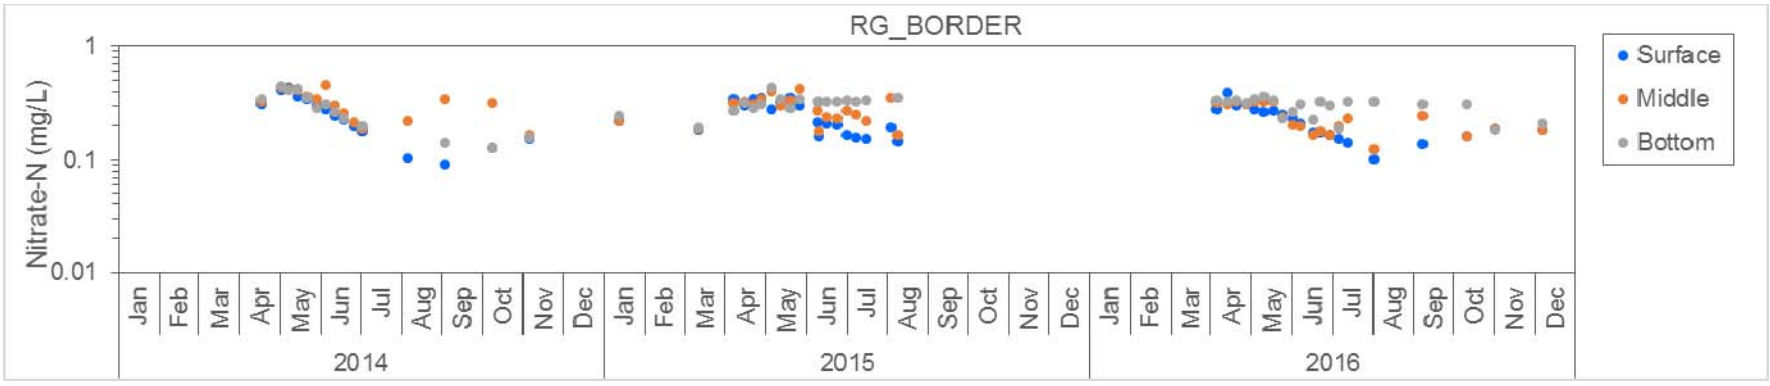

Figure B.4: Aqueous Nitrate-Nitrogen Concentrations at the Surface, Middle and Bottom of the Water Column in Koocanusa Reservoir, 2014 to 2016

Note: Stations RG_KERRRD and RG_USELK are upstream of the Elk River. Stations RG_DSELK, RG_USGOLD, RG_GRASMERE, and RG_BORDER are downstream of the Elk River.

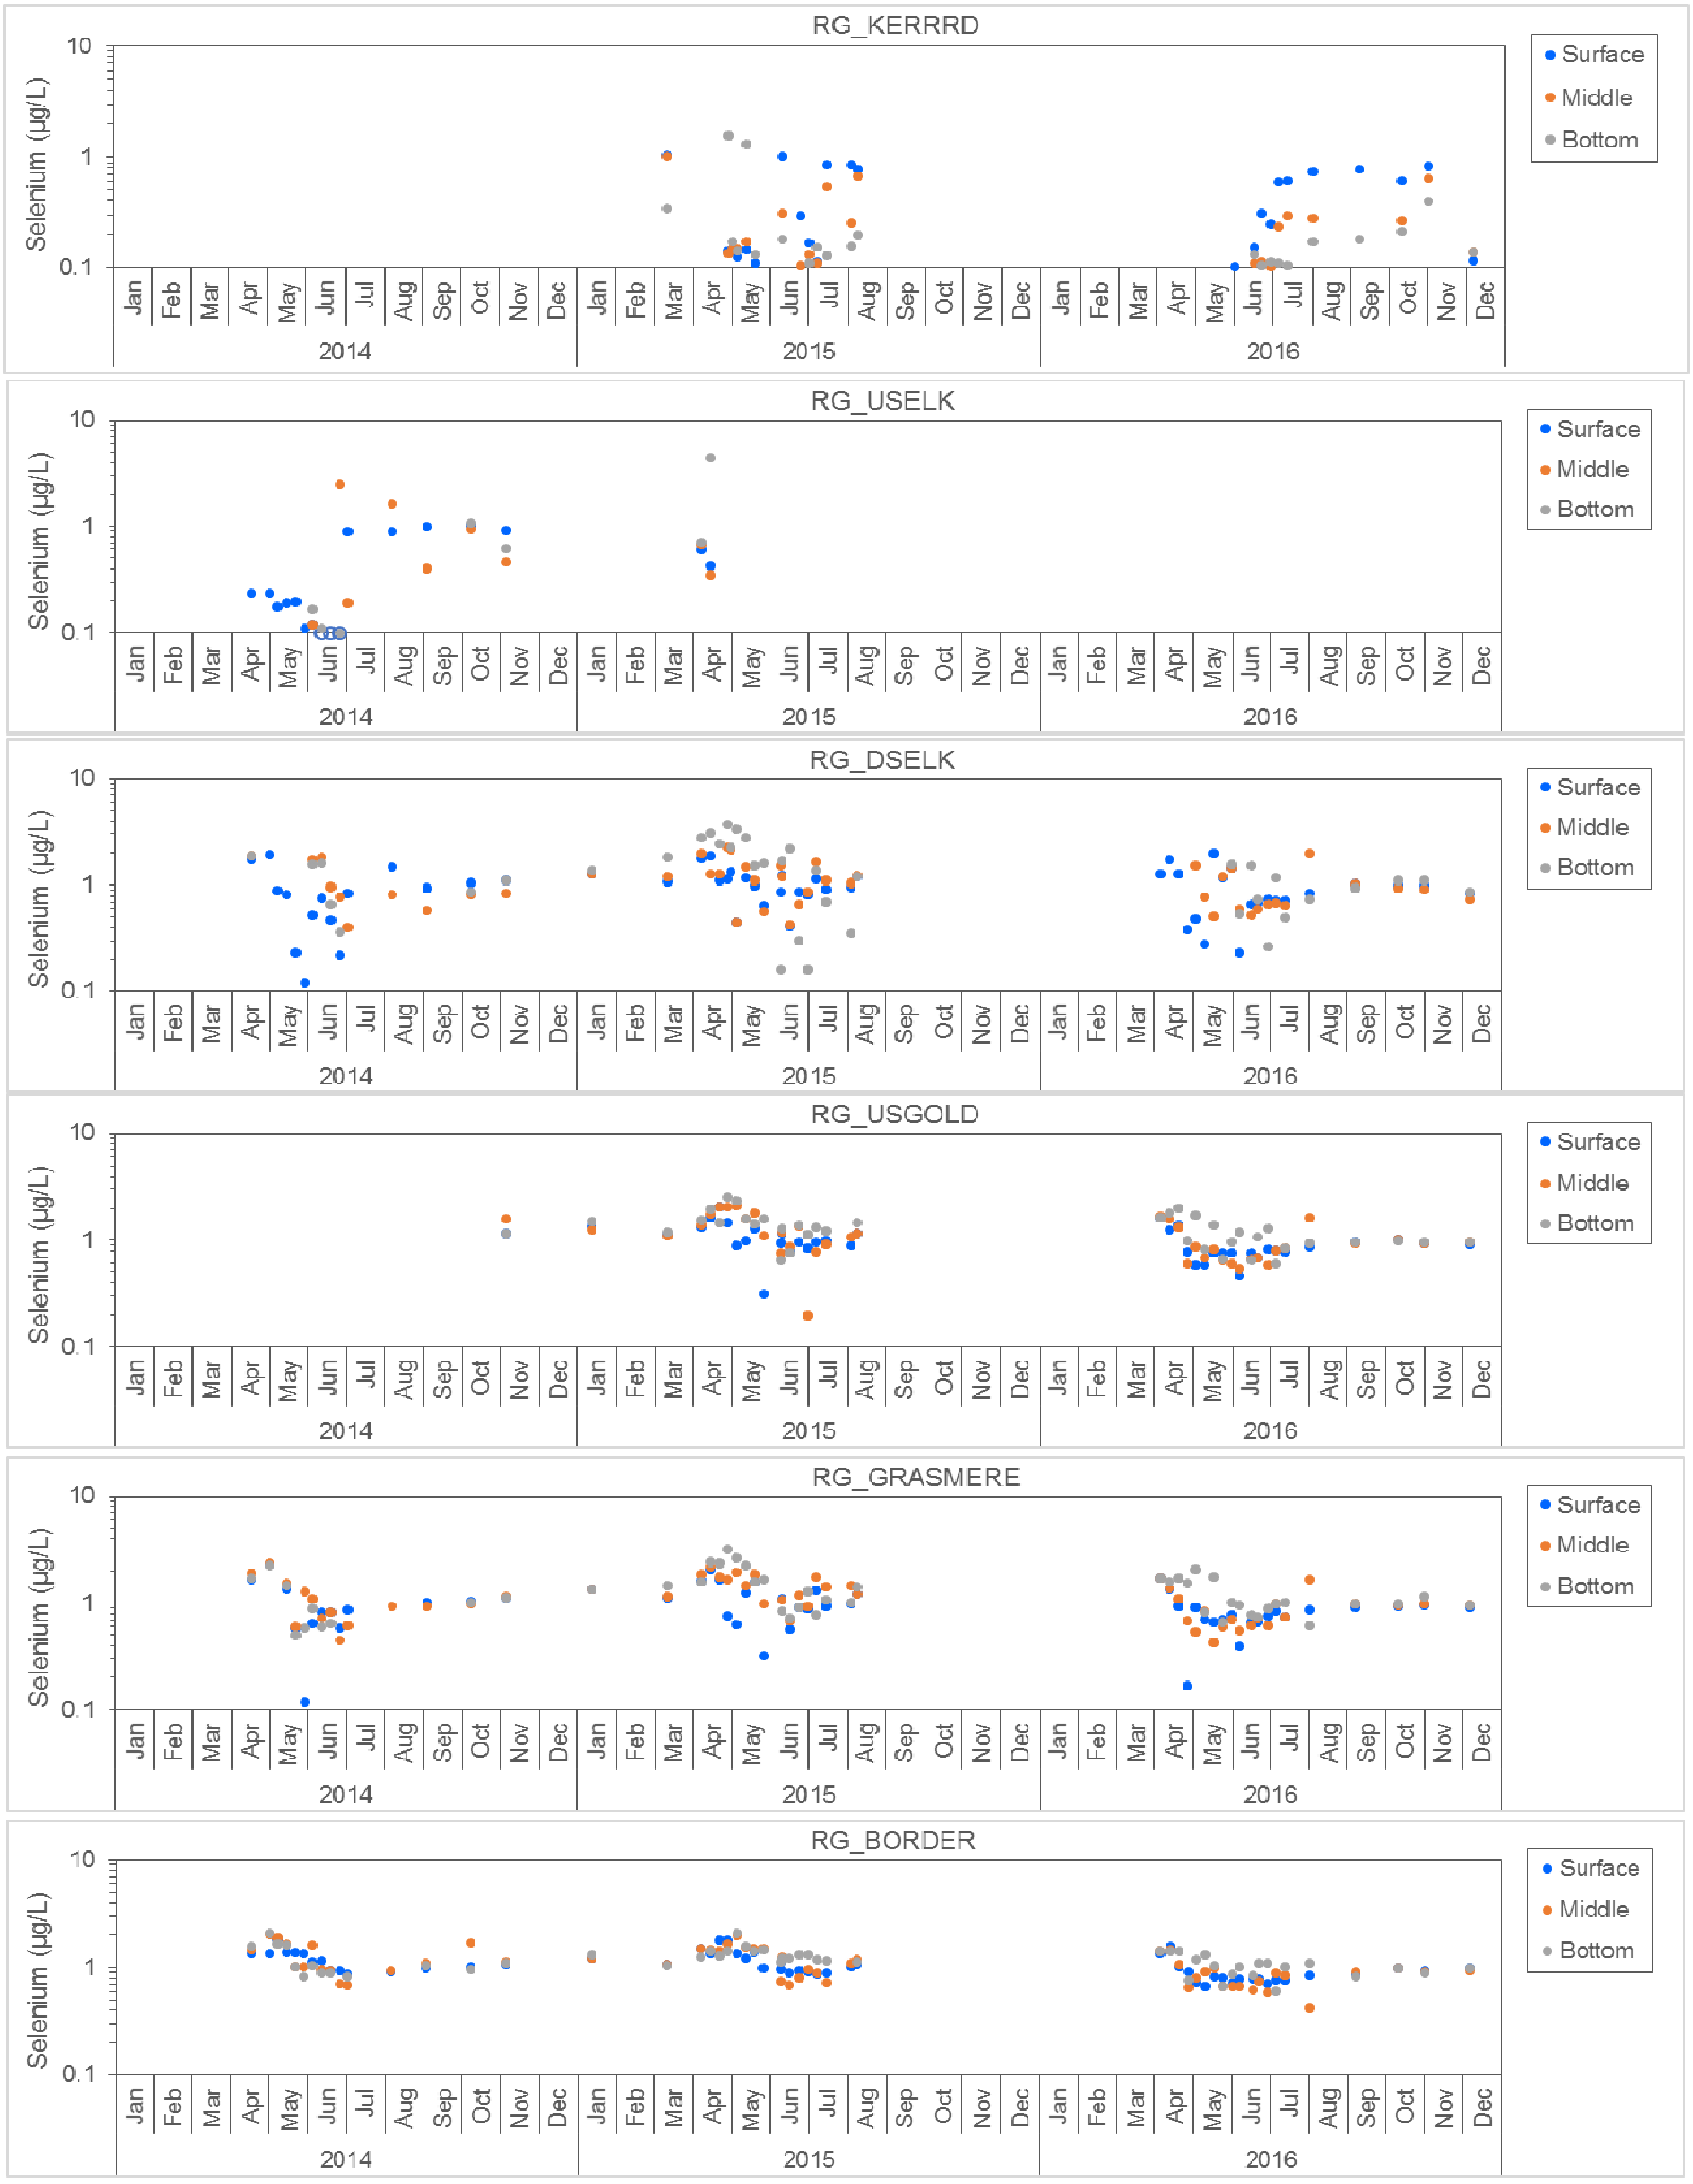

Figure B.5: Aqueous Total Selenium Concentrations at the Surface, Middle and Bottom of the Water Column in Koocanusa Reservoir, 2014 to 2016

Note: Stations RG_KERRRD and RG_USELK are upstream of the Elk River. Stations RG_DSELK, RG_USGOLD, RG_GRASMERE, and RG_BORDER are downstream of the Elk River.

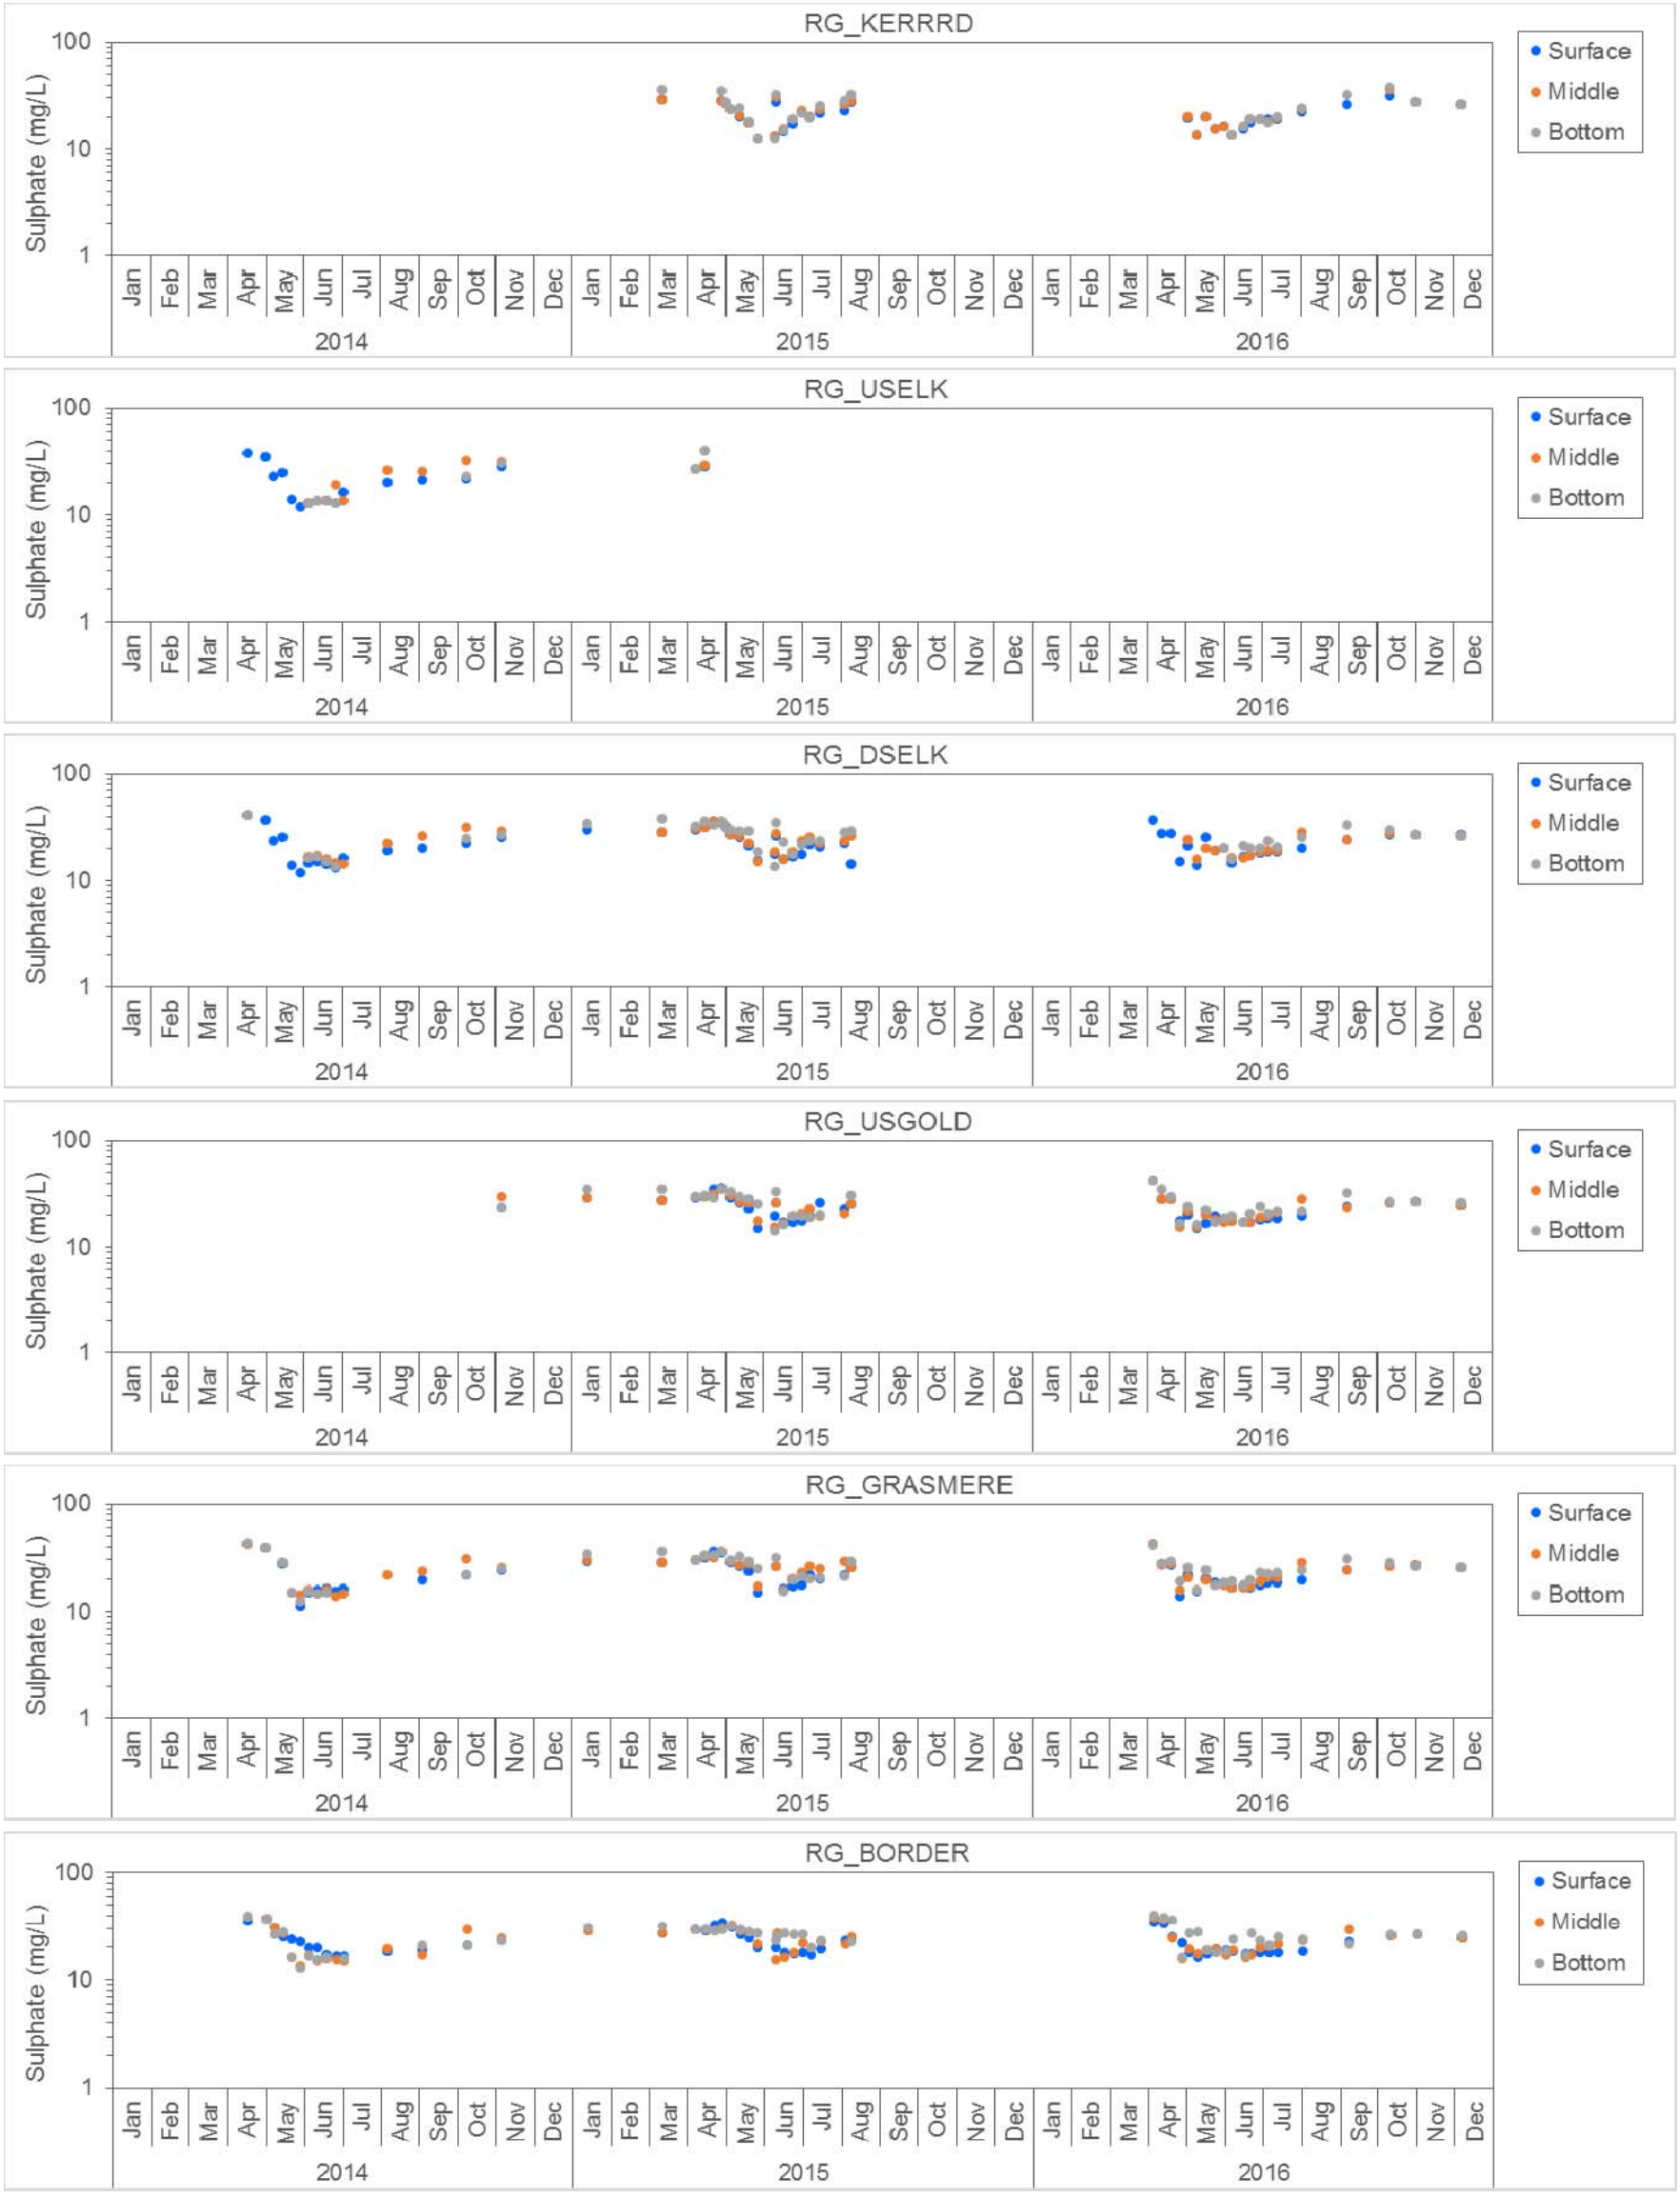

Figure B.6: Aqueous Sulphate Concentrations at the Surface, Middle and Bottom of the Water Column in Koocanusa Reservoir, 2014 to 2016

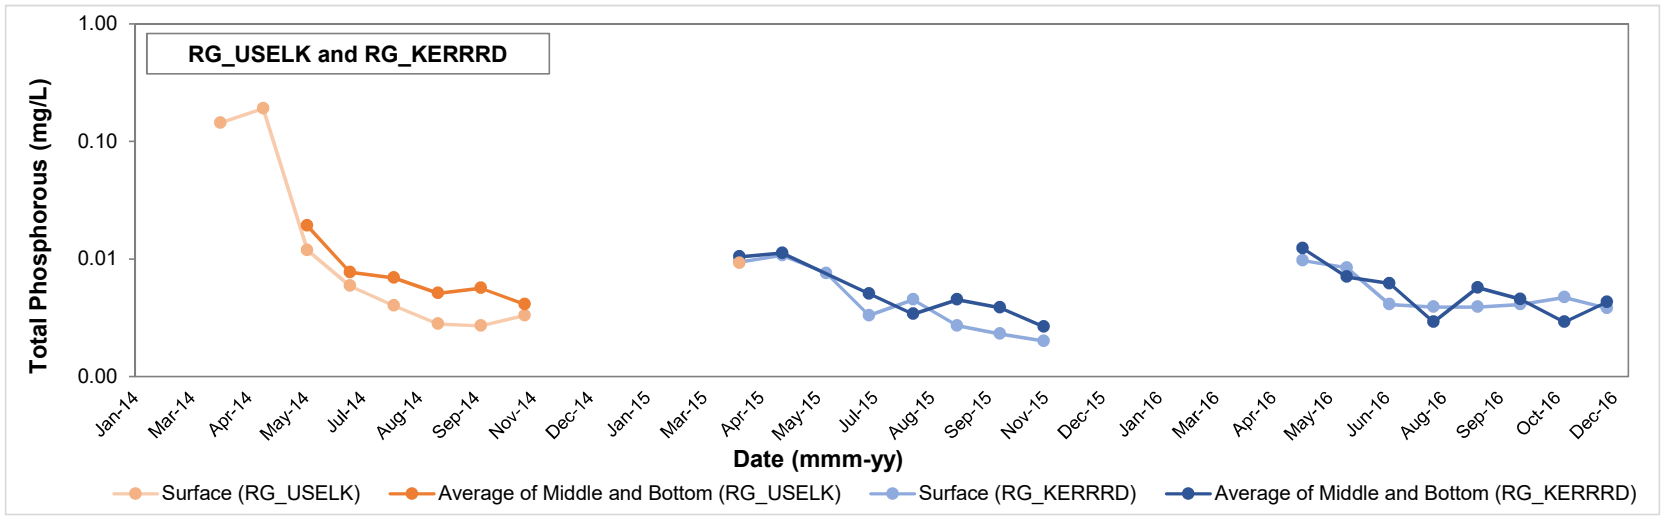
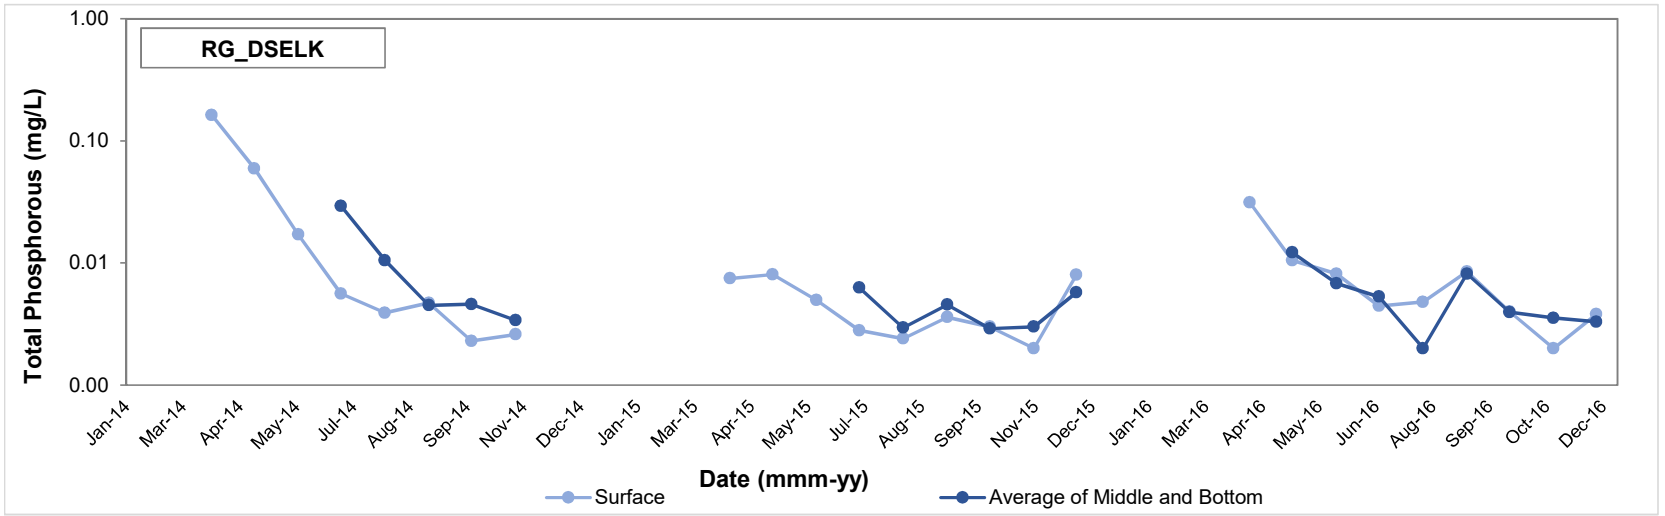
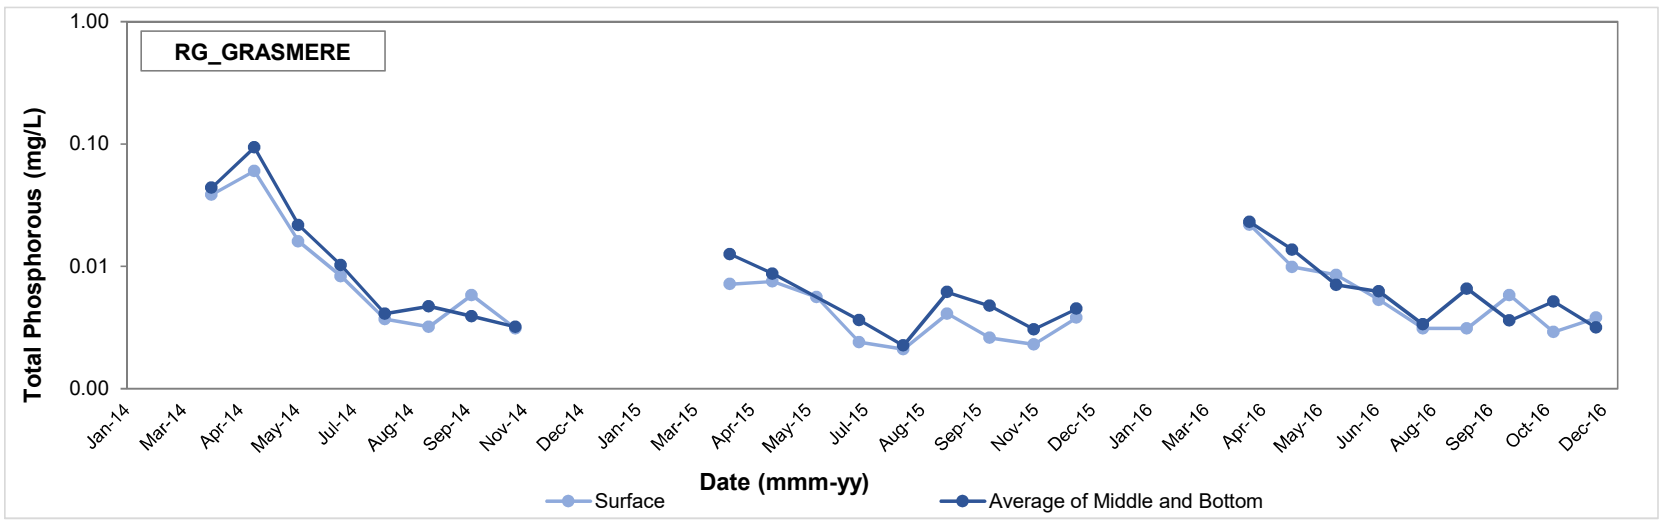
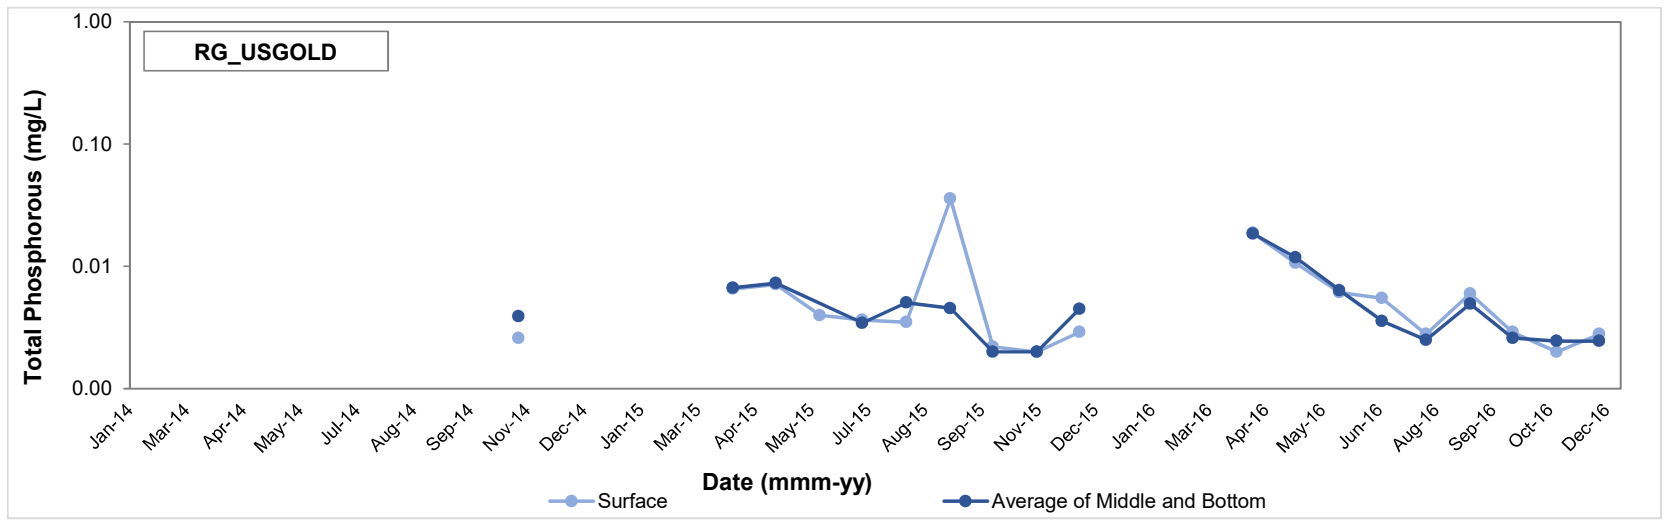
Note: Stations RG_KERRRD and RG_USELK are upstream of the Elk River. Stations RG_DSELK, RG_USGOLD, RG_GRASMERE, and RG_BORDER are downstream of the Elk River.









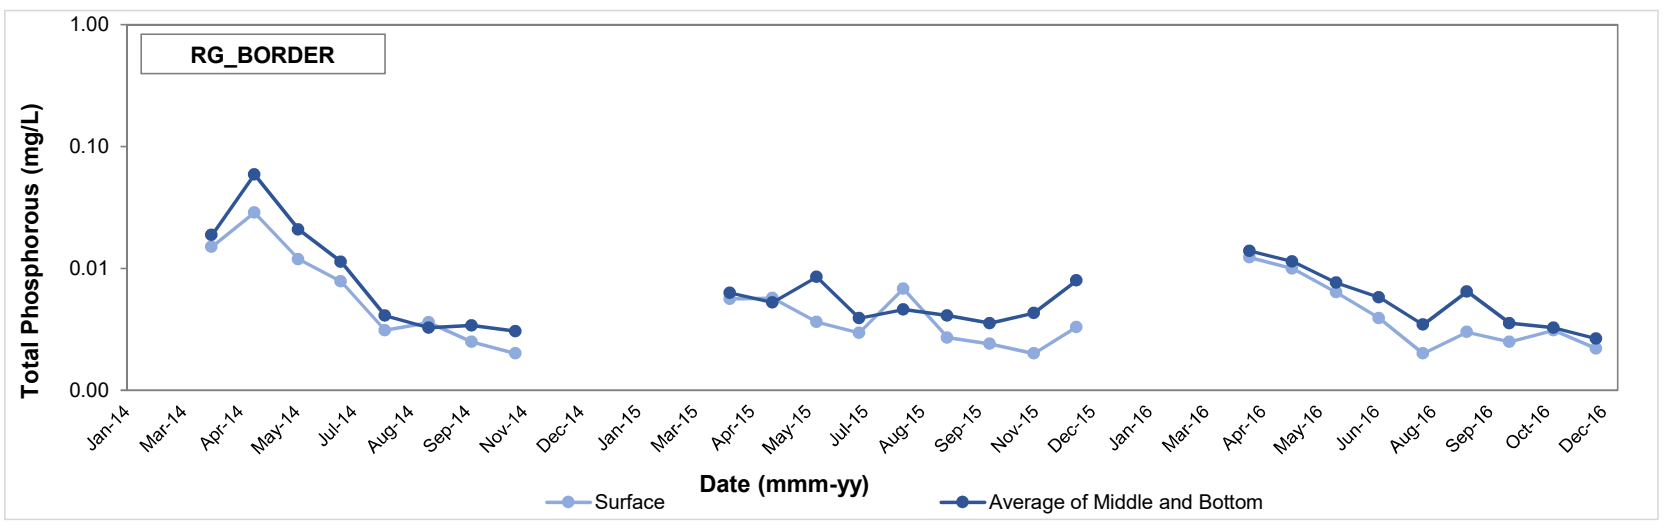


Figure B.7: Mean Monthly Total Phosphorous Concentrations in Koocanusa Reservoir, 2014 to 2016

Notes: Stations RG_USELK and RG_KERRRD are located upstream of the Elk River and stations RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER are located downstream. RG_USELK was only sampled in 2014, as the station was moved further upstream for the 2015 sampling program to RG_KERRRD.

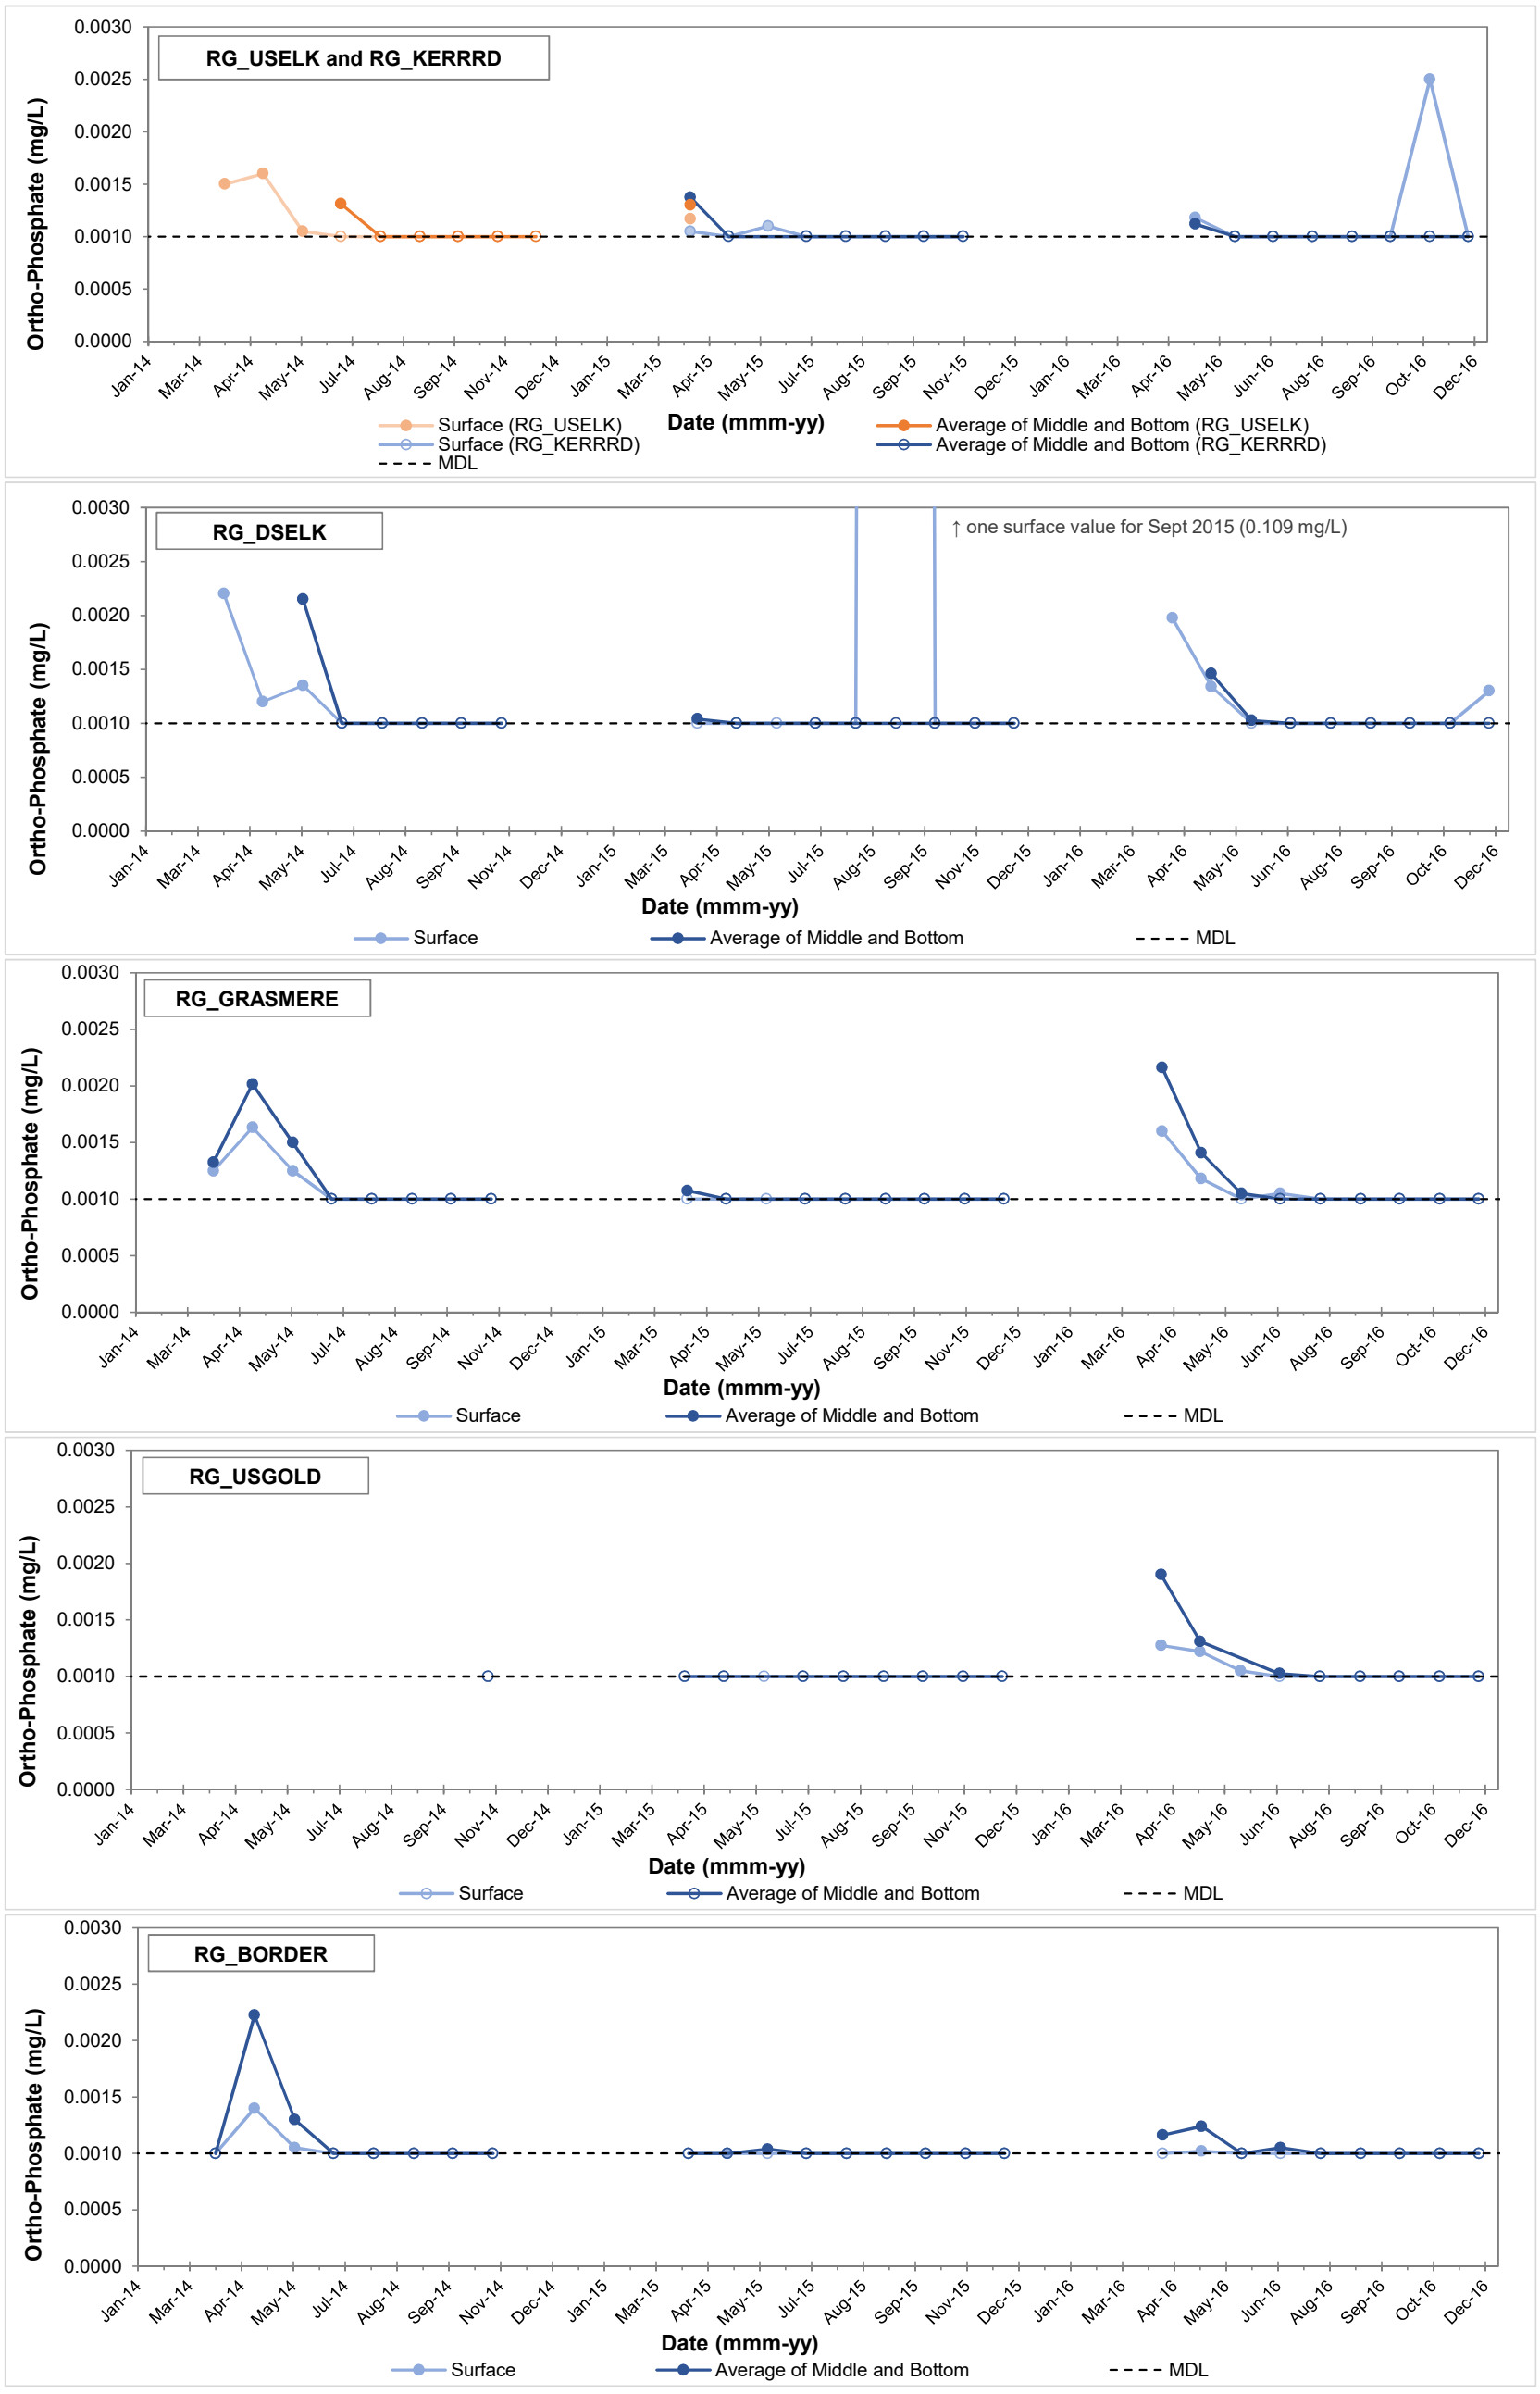

Figure B.8: Mean Monthly Ortho-Phosphate Concentrations in Koocanusa Reservoir, 2014 to 2016

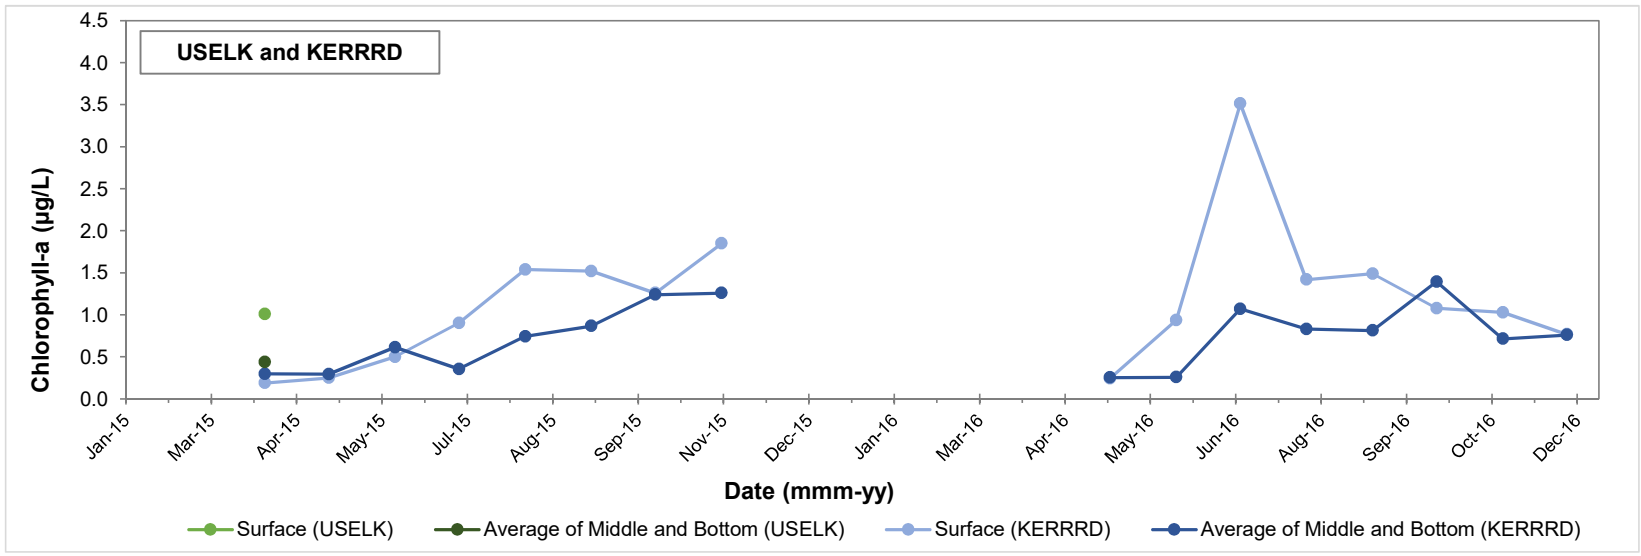
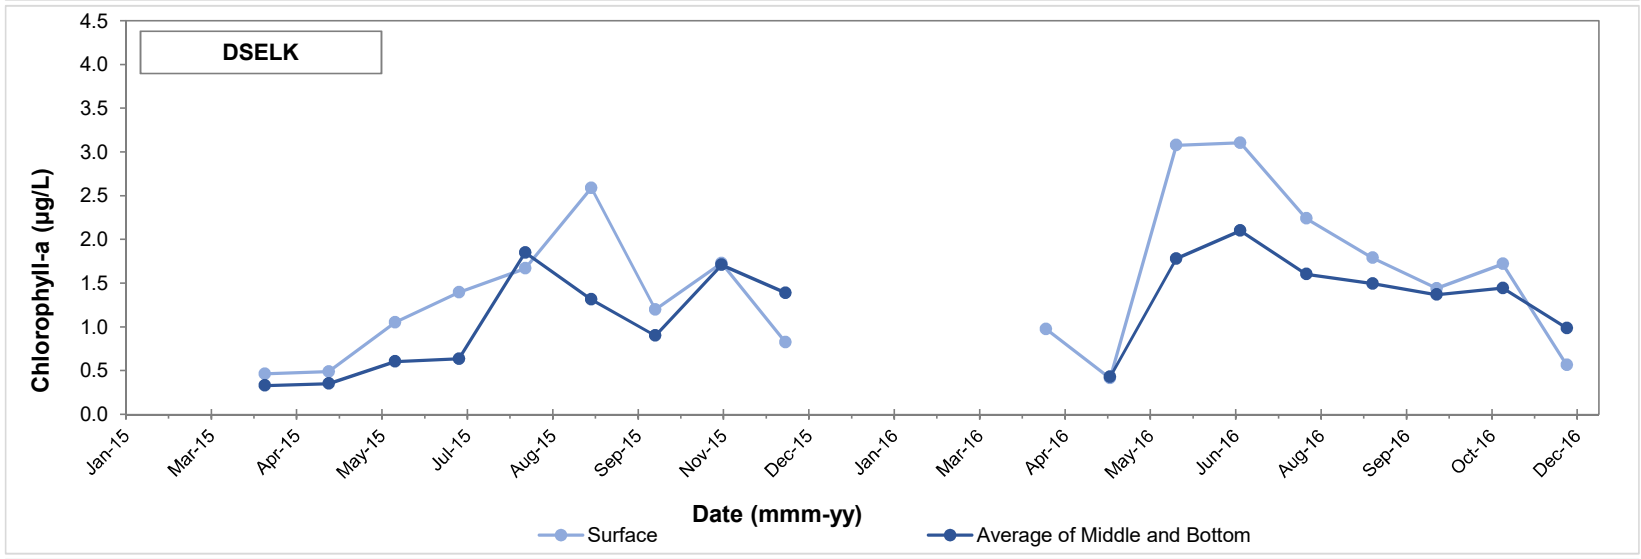
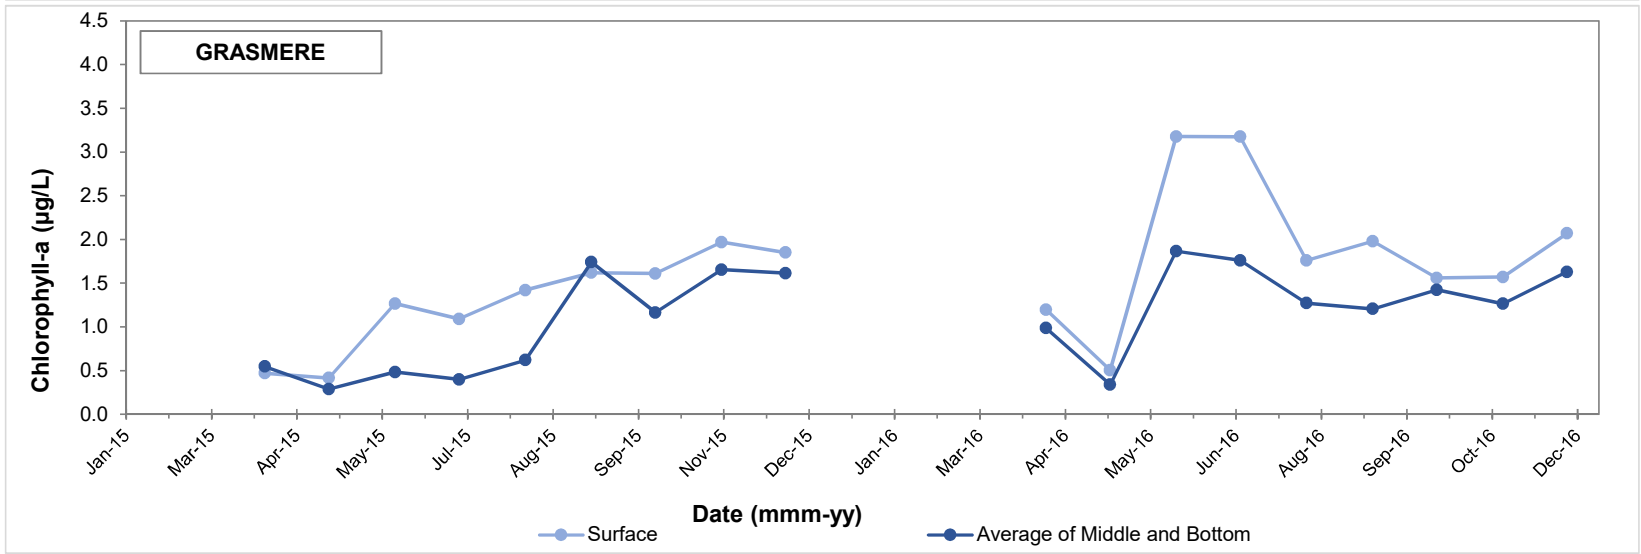
Notes: Stations RG_USELK and RG_KERRRD are located upstream of the Elk River and stations RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER are located downstream. RG_USELK was only sampled in 2014, as the station was moved further upstream for the 2015 sampling program to RG_KERRRD.
Open markers represent values at the method detection limit (MDL).

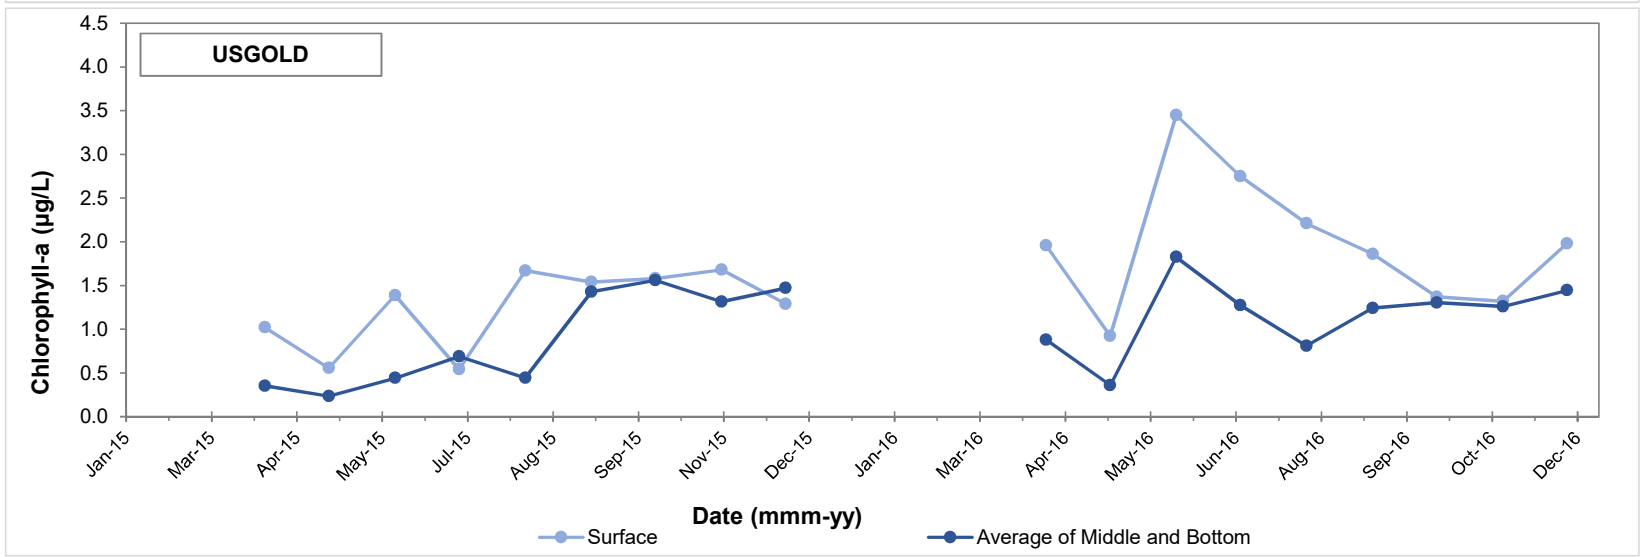
Figure B.9: Mean Monthly Secchi Depths in Koocanusa Reservoir, 2015 to 2016

Notes: No data for Secchi depth were collected in 2014. RG_KERRRD is located upstream of the Elk River and stations RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER are located downstream.









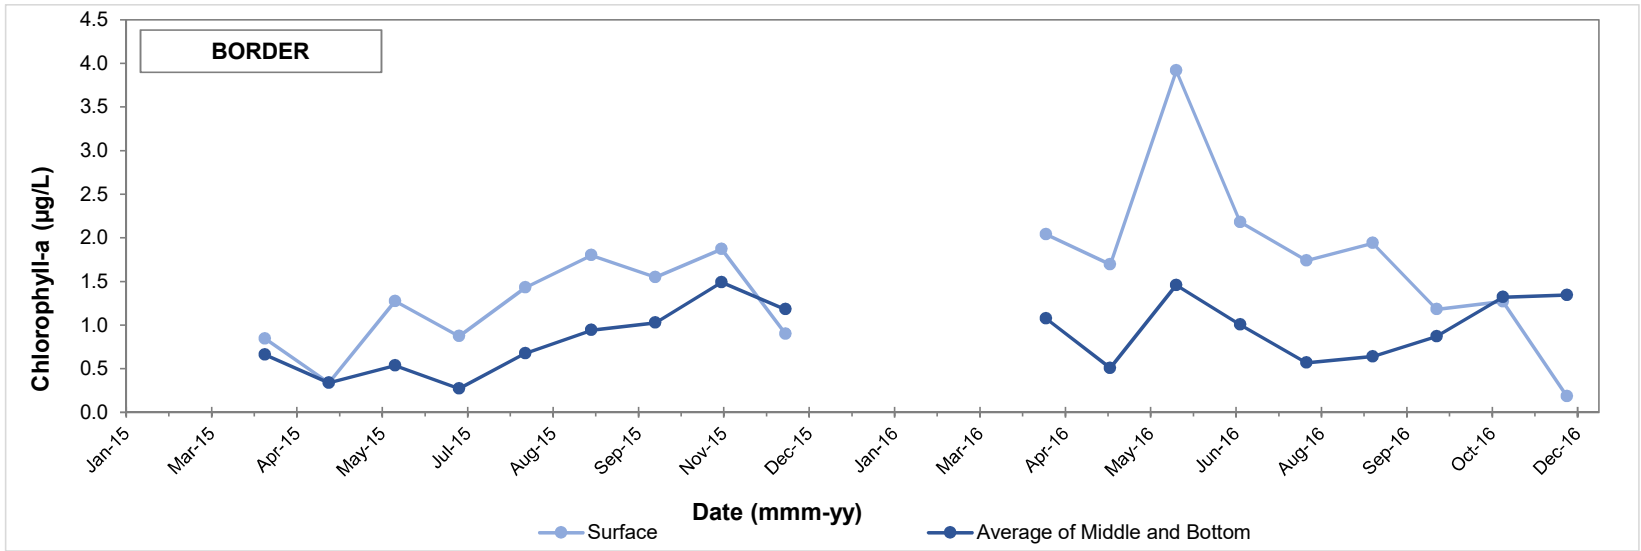


Figure B.10: Chlorophyll-a Concentrations (in µg/L) at Water Quality Monitoring Stations in Koocanusa Reservoir Upstream (USELK and KERRRD) and Downstream (DSELK, GRASMERE, USGOLD, BORDER) from the Elk River, 2015 and 2016

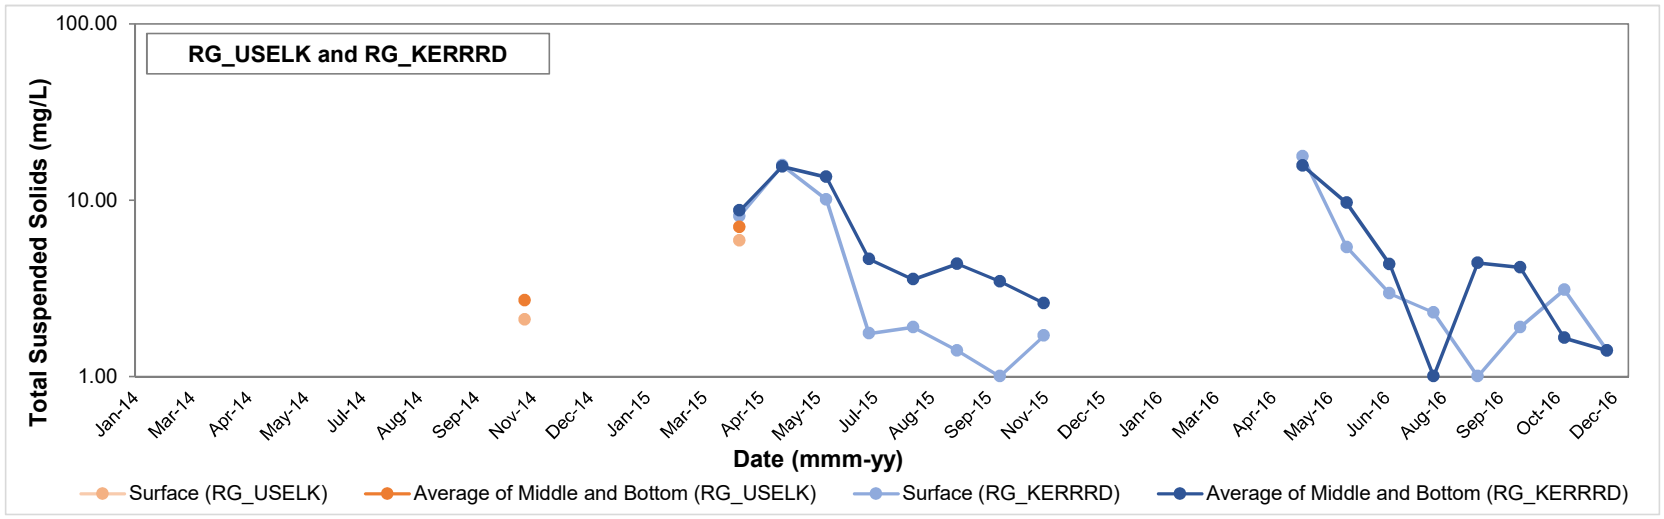
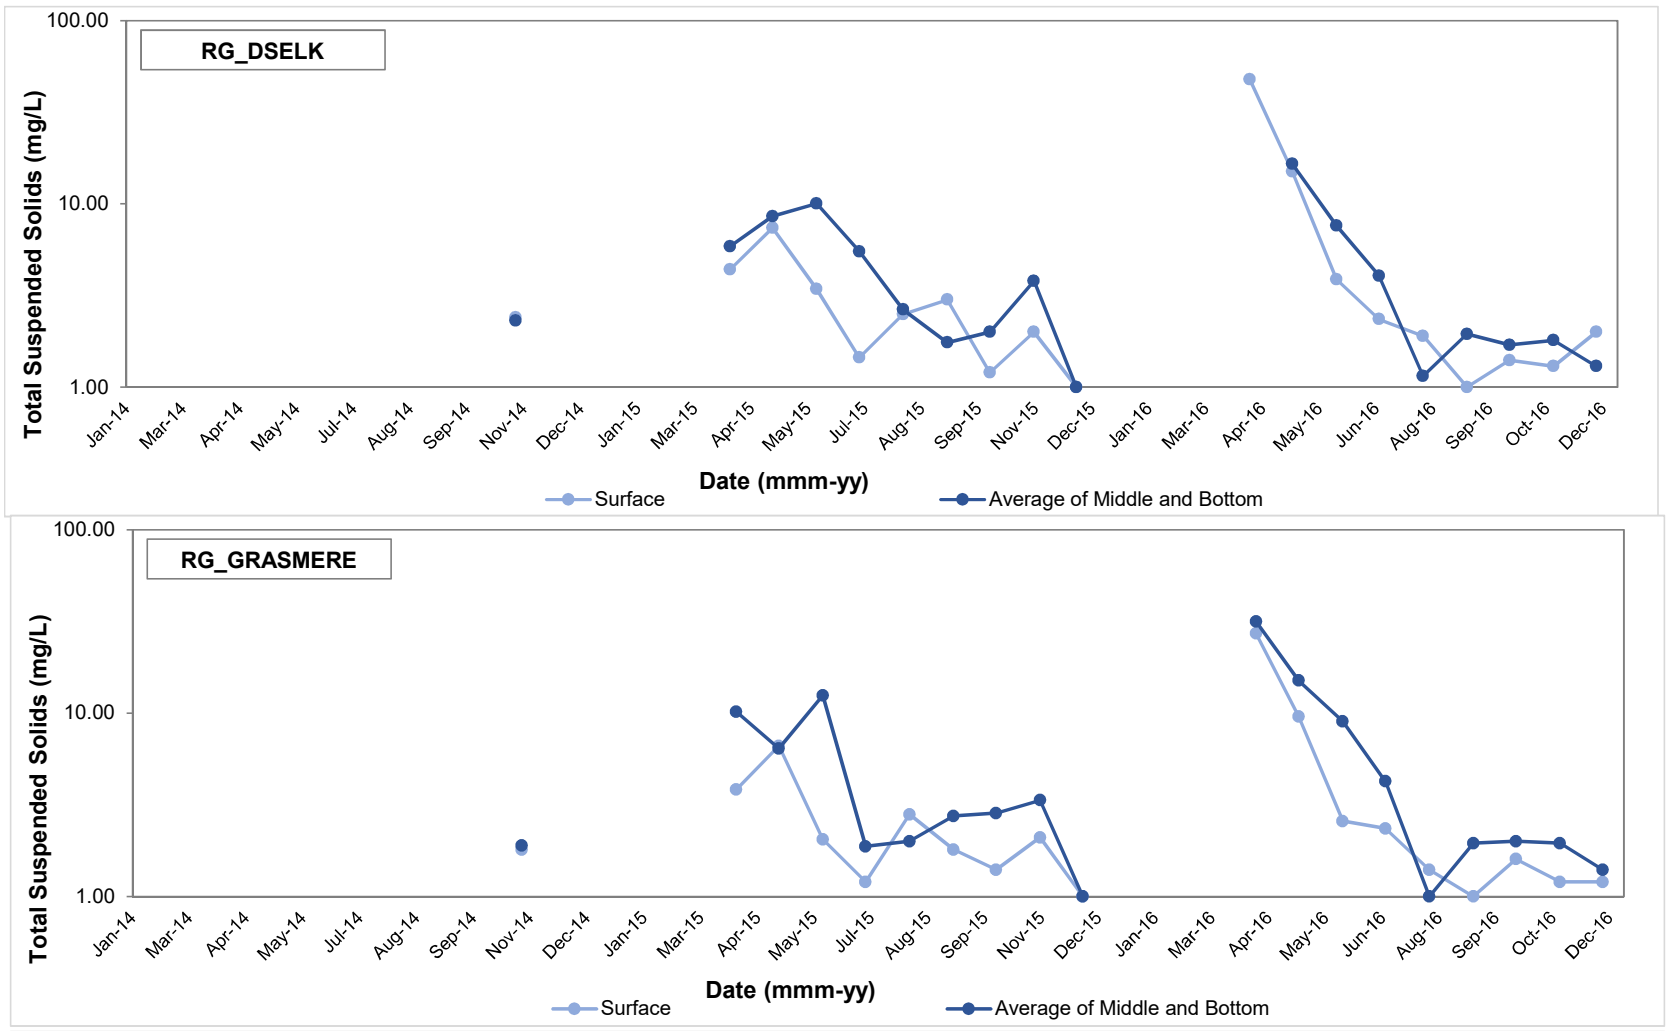
Note: Chlorophyll-a was not monitored in 2014.





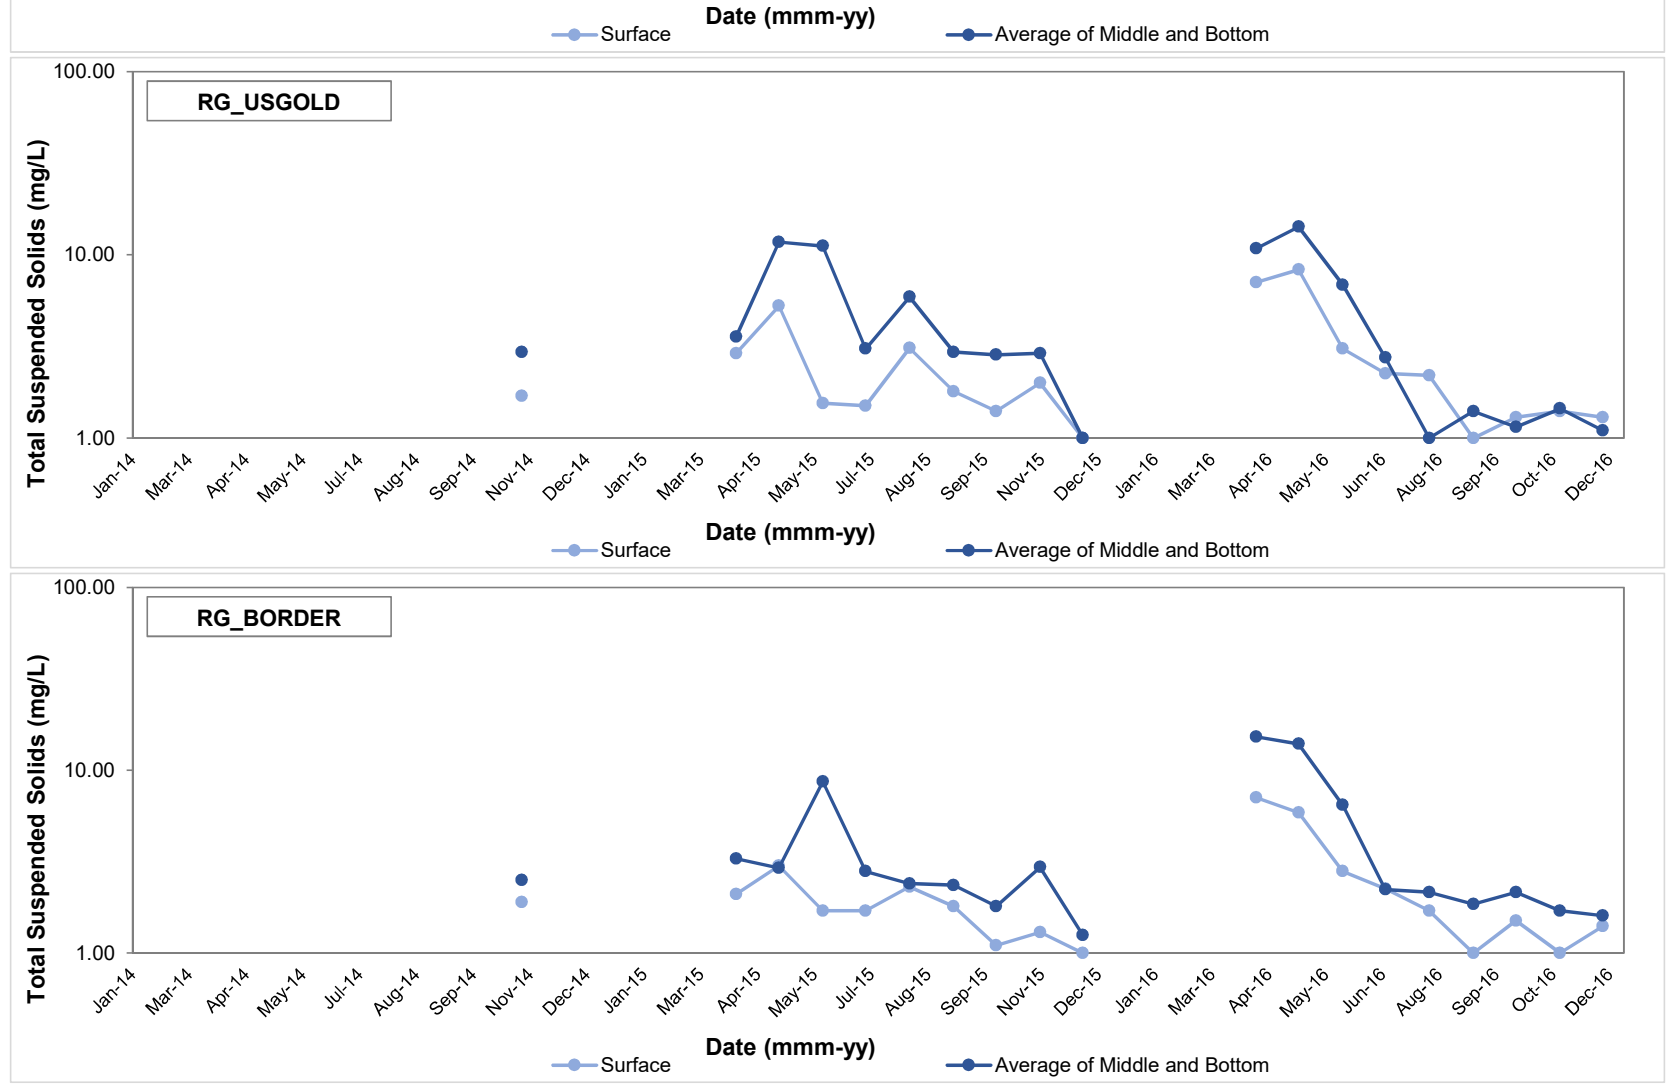


Figure B.11: Mean Monthly Total Suspended Solids Concentrations in Koocanusa Reservoir, 2014 to 2016

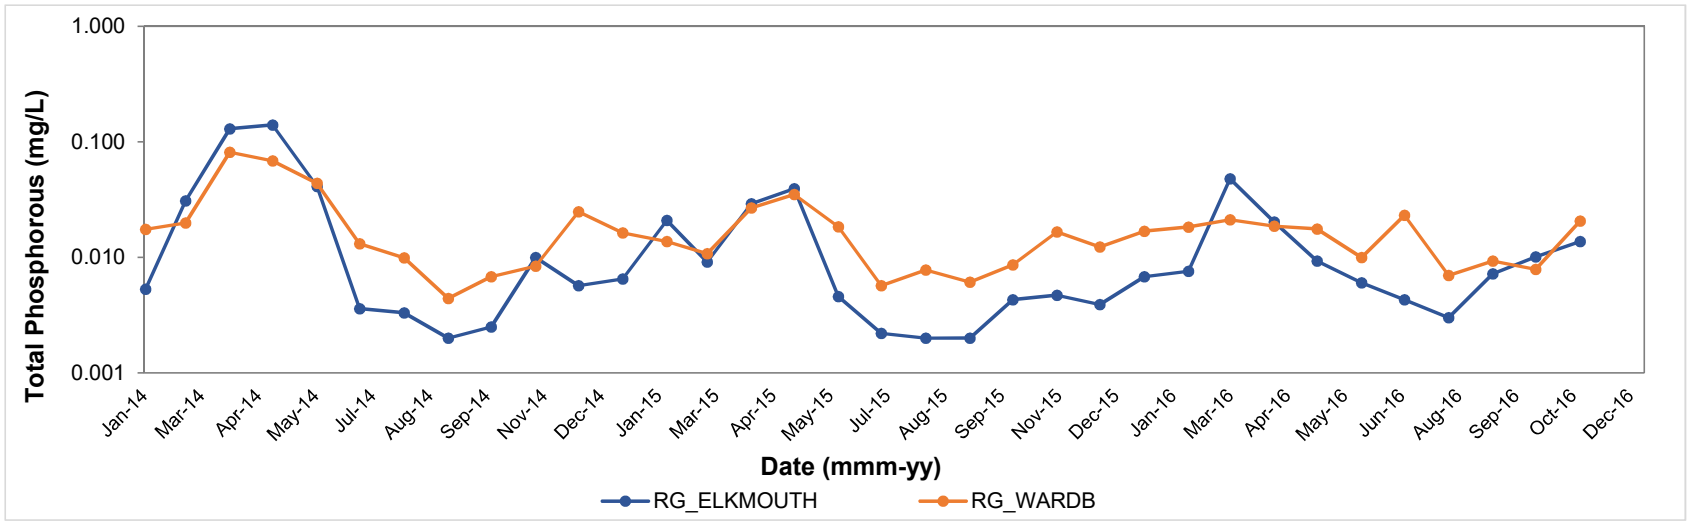
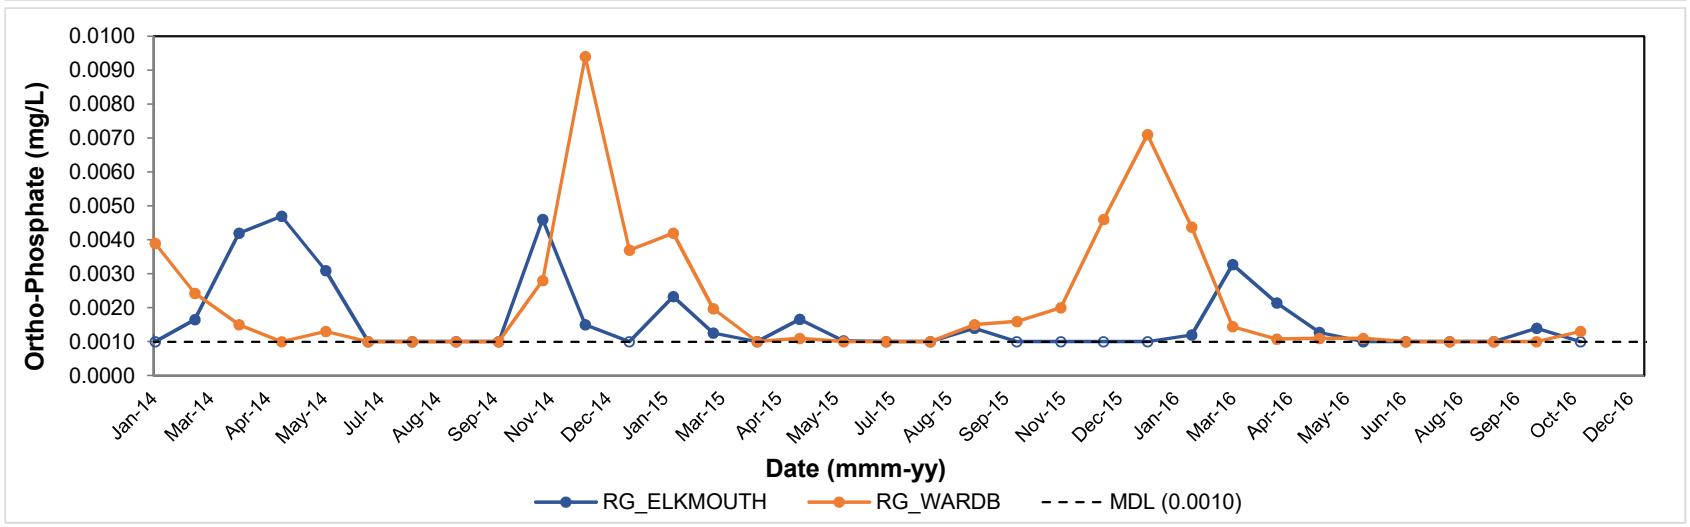
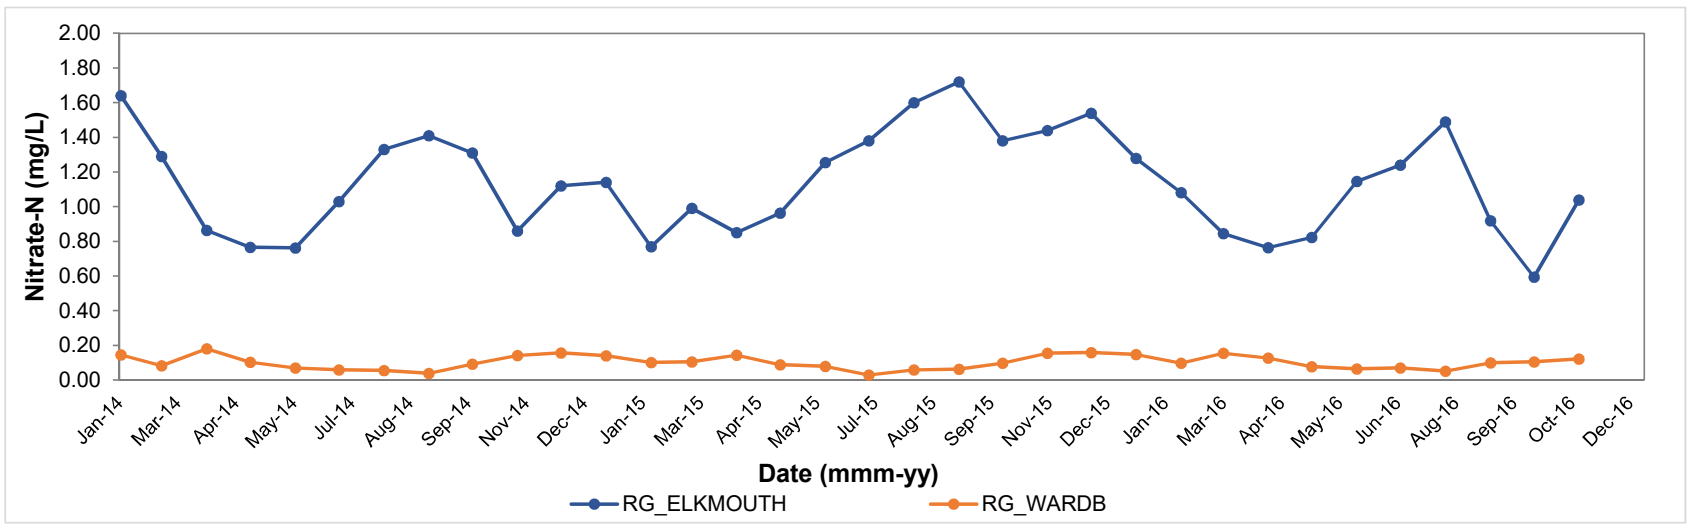
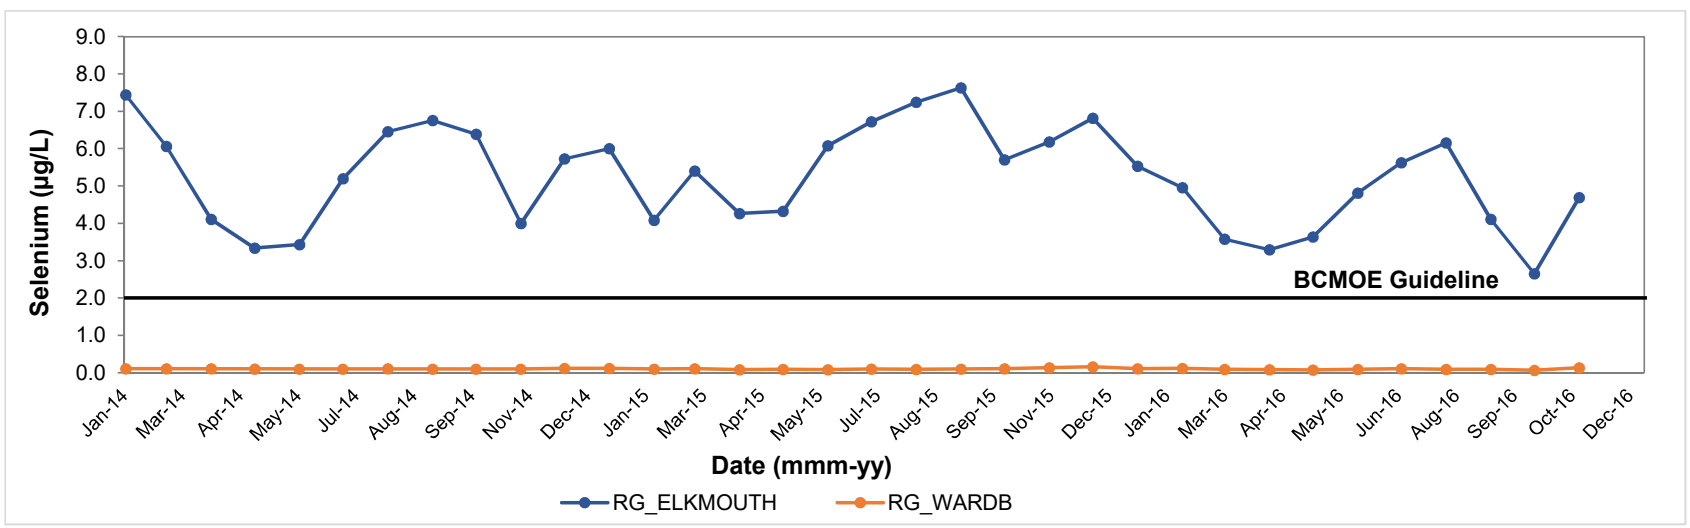
Notes: Stations RG_USELK and RG_KERRRD are located upstream of the Elk River and stations RG_DSELK, RG_GRASMERE, RG_USGOLD, and RG_BORDER are located downstream. RG_USELK was only sampled in 2014, as the station was moved further upstream for the 2015 sampling program to RG_KERRRD.









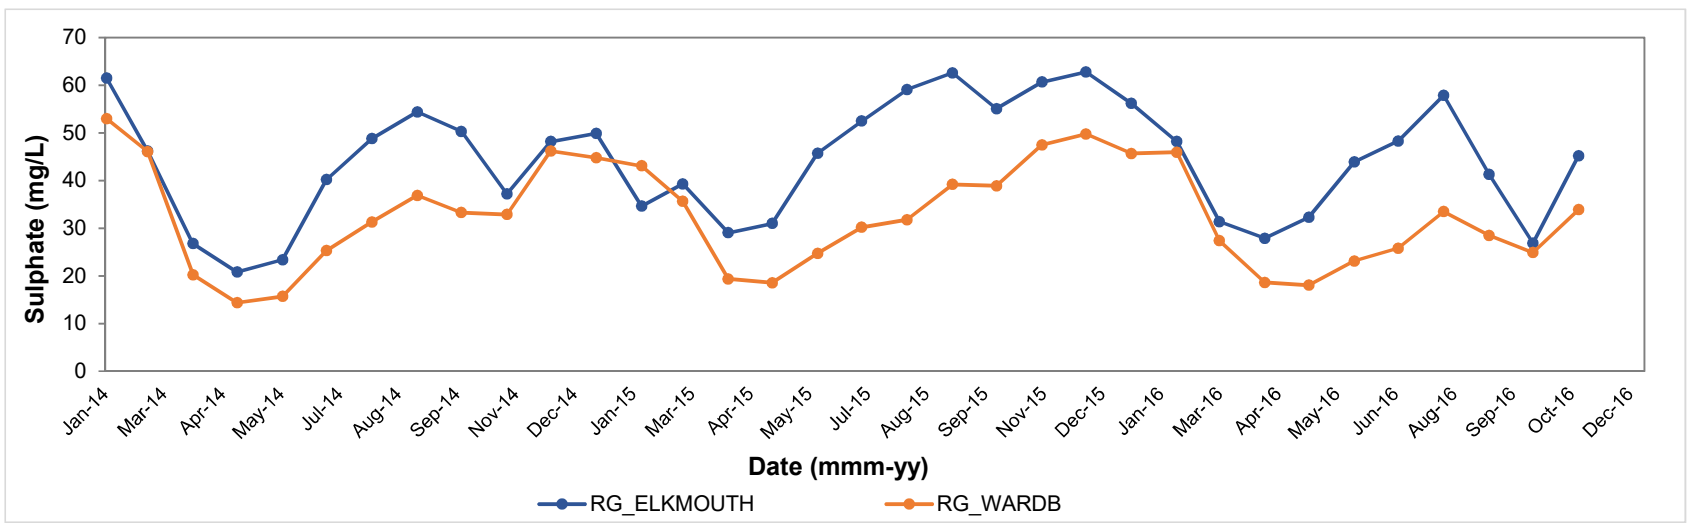


Figure B.12: Mean Monthly Total Phosphorous, Ortho-Phosphate, Nitrate-Nitrogen, Selenium, and Sulphate Concentrations in the Kootenay River (RG_WARDB) and the Elk River (RG_ELKMOUTH), 2014 to 2016

Note: Open markers represent values at the method detection limit (MDL).

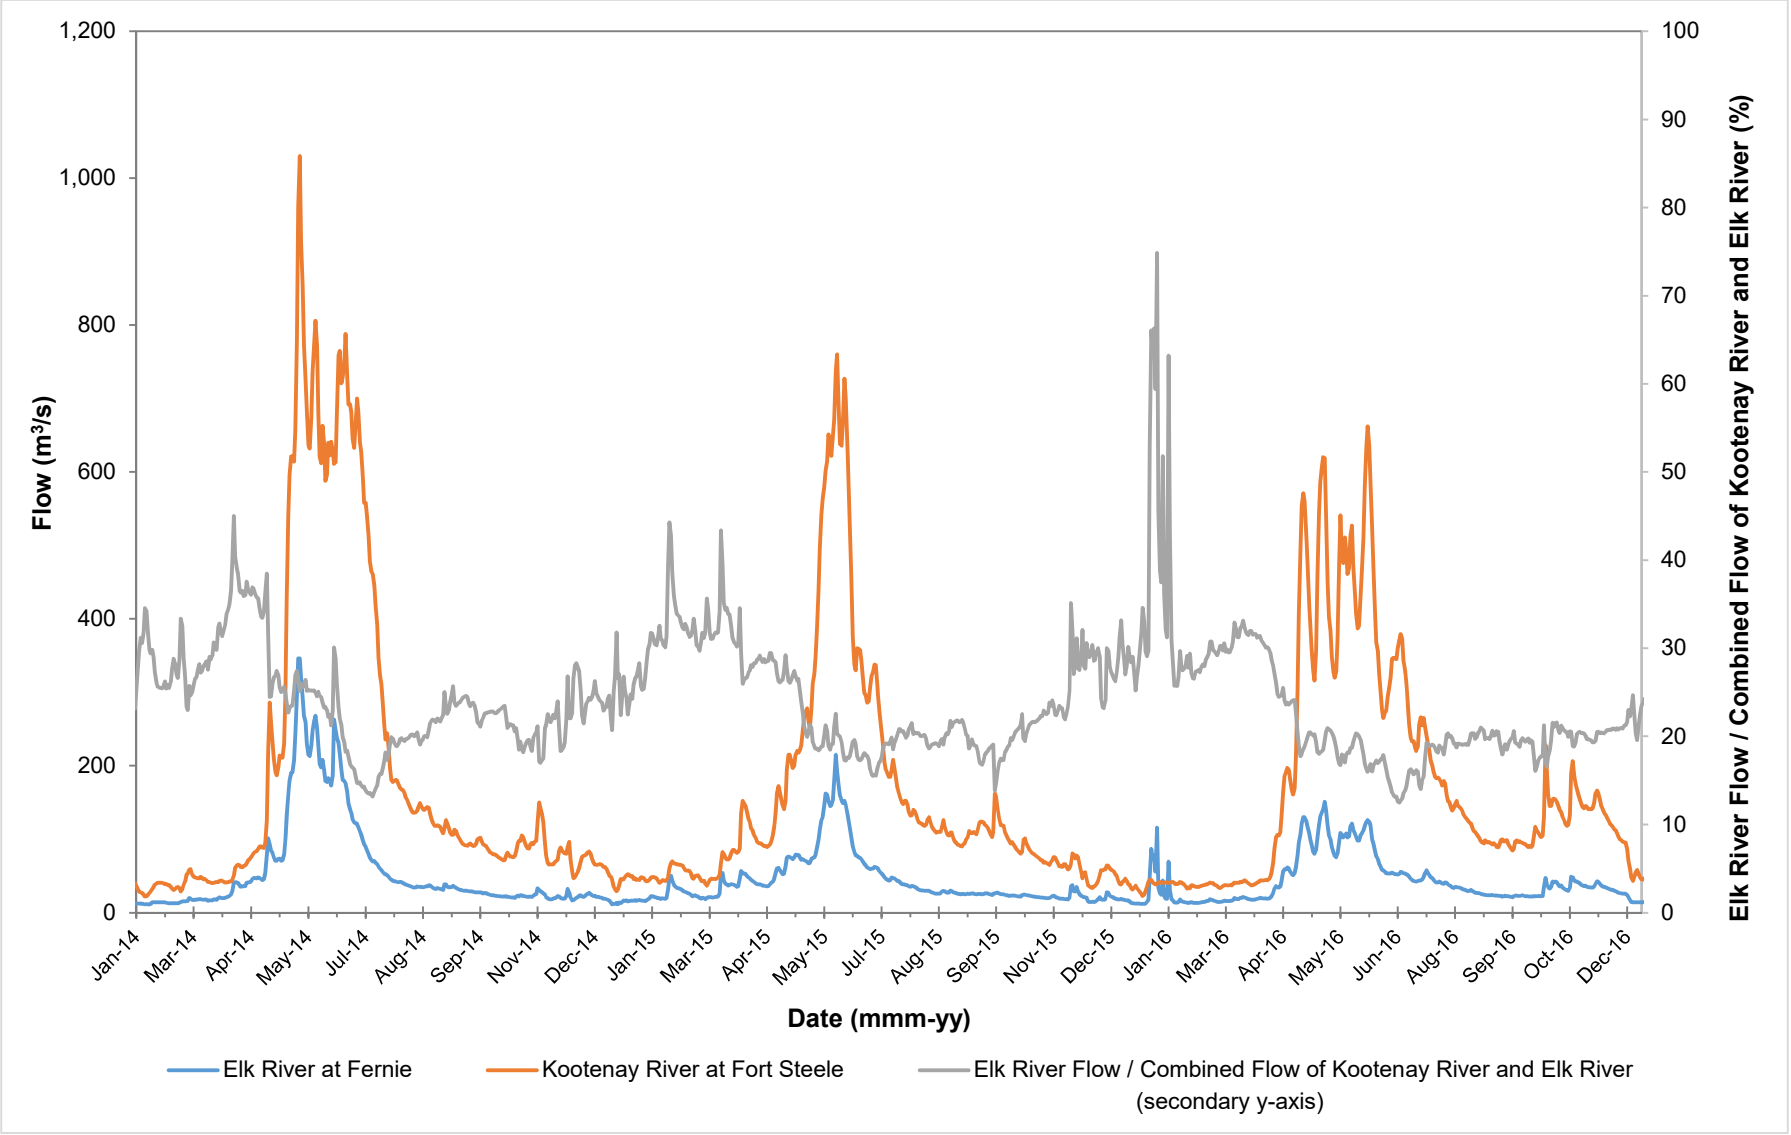

Figure B.13: Flow Measurements at the Elk River (Station No. 08NK002) and Kootenay River (Station No. 08NG065) Water Survey of Canada Stations, 2014 to 2016

Table B.1: *In situ* Water Quality Measurements in Koocanusa Reservoir, 2014

[1] Gold Creek was not sampled in February 2015, as ice was too thin to traverse safely.
* BGA-PC - blue-green algae phycocyanin - a measurement of the amount of cyanobacteria in the water column.
* NR - Readings were not reliable (NR), as oxygen optical probe was malfunctioning. Manufacturer indicated that values provided by meter were reliable and representative of the conditions, as malfunction was related to water fowling of internal components and would not impede the accuracy of the readings.

Note: Monitoring upstream of the Elk River began in 2014 at RG_USELK and then was moved to RG_KERRRD, farther upstream, in April 2015.

* Suspect value, not included in summary tables or plots.

Table B.5: Selected Water Quality Data for the RG_KERRRD Water Quality Monitoring Station in Koocanusa Reservoir Upstream of the Elk River, 2015 and 2016

	Date	Total Phosphorus		Orthophosphate		Dissolved Cadmium (Cd)		Nitrate-Nitrogen (NO_3)		Nitrite-Nitrogen (NO_2)		Ammonia-Nitrogen (NH_3)		Total Kjeldahl Nitrogen		Total Selenium (Se)		Sulphate (SO_4)	
		mg/L		mg/L		mg/L		mg/L		mg/L		mg/L		mg/L		mg/L		mg/L	
		Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom	Surface	Average of Middle and Bottom
